Daily Deliveries [32P]: You pick the day.

We're pleased to announce that a new and better production method enables us to make our dNTP, [α -³²P]- and ATP, [γ -³²P]- available from stock every day at catalog specifications.

Now you can order any day for shipment within 24 hours. Or order Thursday for Monday delivery. You'll get the purest and most stable ³²P nucleotides available.

Ready when you are

ATP, [γ -³²P]-

>7000Ci/mmol	Tricine
1000-3000Ci/mmol	Tricine
1000-3000Ci/mmol	Aqueous
10-50Ci/mmol	Aqueous
2-10Ci/mmol	Aqueous

dNTP, [α -³²P]-

>600Ci/mmol	Ethanol:Tricine
>600Ci/mmol	Tricine
~3000Ci/mmol	Tricine

4015

HPLC makes the difference

By introducing preparative HPLC technology into our manufacturing process, we not only improved production efficiency, but purity and stability as well. In fact, extensive testing convinces us that no other manufacturer can match the reproducibility and

reliability of these nucleotides.

Send for our complete ³²P nucleotides listing.

GUIDE TO AUTHORS

Authors should be aware of the diversity of *Nature's* readership and should strive to be as widely understood as possible.

Review articles should be accessible to the whole readership. Most are commissioned, but unsolicited reviews are welcome (in which case prior consultation with the office is desirable).

Scientific articles are research reports whose conclusions are of general interest or which represent substantial advances of understanding. The text should not exceed 3,000 words and six displayed items (figures plus tables). The article should include an abstract of about 50 words.

Letters to *Nature* are ordinarily 1,000 words long with no more than four displayed items. The first paragraph (not exceeding 150 words) should say what the letter is about, why the study it reports was undertaken and what the conclusions are.

Matters arising are brief comments (up to 500 words) on articles and letters recently published in *Nature*. The originator of a Matters Arising contribution should initially send his manuscript to the author of the original paper and both parties should, wherever possible, agree on what is to be submitted.

Manuscripts may be submitted either to London or Washington (decisions being made only in London). Manuscripts should be typed (double spacing) on one side of the paper only. Three copies are required, each accompanied by copies of lettered artwork. No title should exceed 80 characters in length. Reference lists, figure legends, etc. should be on separate sheets, all of which should be numbered. Abbreviations, symbols, units, etc. should be identified on one copy of the manuscript at their first appearance.

References should appear sequentially indicated by superscripts in the text and should be abbreviated according to the *World List of Scientific Periodicals*, fourth edition (Butterworth 1963-65). The first and last page numbers of each reference should be cited. References to books should clearly indicate the publisher and the date and place of publication. Unpublished articles should not be formally referred to unless accepted or submitted for publication, but may be mentioned in the text.

Each piece of artwork should be clearly marked with the author's name and the figure number. Original artwork should be unlettered. Suggestions for cover illustrations are welcome. Original artwork (and one copy of the manuscript) will be returned when manuscripts cannot be published.

Requests for permission to reproduce material from Nature should be accompanied by a self-addressed (and, in the case of the UK and USA, stamped) envelope.

order requesting invoice to:

Stephen J. O'Brien, Editor
GENETIC MAPS
Building 560, Room 11-85
National Cancer Institute
Frederick, Maryland 21701

Edited by Stephen J. O'Brien

The second and totally revised edition of **GENETIC MAPS** is now available. **GENETIC MAPS** contains updated linkage, restriction, and mtDNA maps of over 50 organisms including λ , SV40, Φ X174, HSV1,2, E. coli, S. typhimurium, B. subtilis, N. crassa, Chlamydomonas, S. cerevisiae, C. elegans, Drosophila, mouse, cat, rabbit, 7 primates, man, corn, wheat and many more (70 maps total). Each map consists of a table of mapped loci, references for each, and an illustrated map of the 1982 status. At last, all the major gene maps are compiled in a single convenient handbook for easy reference. And, even better, **GENETIC MAPS** will be updated every two years.

The Editor:

Stephen J. O'Brien, Chief, Section of Genetics
Laboratory of Viral Carcinogenesis
National Cancer Institute, U.S.A.

The Contributors:

Nature in Poland

Readers wishing to subscribe to a weekly copy of *Nature* on behalf of a colleague in Poland (where hard currency is scarce) should send a cheque for £50 (or the equivalent in any currency), accompanied by their name and address and that of the proposed recipient, to the *Nature* office in London or New York (see addresses opposite page 95). For further details, readers are referred to *Nature* 3 June, p.354.

More Mouse/ml

MOUSE AND RAT IMMUNOCHEMISTRY REAGENTS

Let Miles be your source for mouse and rat related reagents. We offer a broad and ever-growing selection of dependable quality reagents for use in your laboratory studies of these animals, their cell lines and associated products.

Our antisera include all the major immunoglobulins, IgG subclasses and some rare ones, including anti-mouse IgD and IgE. Of course we also offer conjugates to many of these antigens. Choose from alkaline phosphatase, peroxidase, fluorescein, rhodamine and biotin labels.

Two of our newest products are immunoglobulin reference sera, for mouse and rat. These are the products you have needed to QA your quantitative procedures.

Additional mouse and rat reagents include pooled sera, albumin and gamma globulin fractions, purified immunoglobulins and quantitative RID kits.

Explore the complete listing of our vialled mouse and rat products. Call or write for our product brochure.

Nature in Poland

Readers wishing to subscribe to a weekly copy of *Nature* on behalf of a colleague in Poland (where hard currency is scarce) should send a cheque for £50 (or the equivalent in any currency), accompanied by their name and address and that of the proposed recipient, to the *Nature* office in London or New York (see addresses opposite page 287). For further details, readers are referred to *Nature* 3 June, p.354.

"A unique guide to biological laboratory products."

The Directory of Biologicals offers life scientists a comprehensive listing of what is on the market and where researchers can order these materials for their work. Designed to meet the day-to-day needs of active biologists searching for the right product to use in the laboratory, its simple alphabetical listings cover all of modern life science research. Clear and easy to use, it lists more than 2,000 products commercially available, with the names and addresses of companies throughout the world that offer them for sale. Telex and telephone numbers give users direct access to sales offices in your area. Company entries also briefly describe each supplier's specialization. A separate section lists products by trade name or registered trademark, keyed to the companies in the guide.

Helpful essays on how to use the directory, safety procedures, how to purchase biological materials, and the future of modern biology, make this the most useful directory ever published for biological research workers.

All subscribers to *Nature** automatically receive a handsome paperbound version of the directory. **But if you think you need a copy to stand up against constant use in your laboratory or your library, or if you are not a subscriber, you can purchase the deluxe hardcover edition.** (No paperback editions will be available after subscribers receive their free copy.) To order a hardcover edition, all you need do is fill out the form and mail it today.

IBF affinity chromatography for molecular genetics

MAJOR BENEFITS :

- Absence of non specific interactions
- No Ligand Leakage
- Ready to use
- Long life time
- High flow rates

— « An IBF support for every chromatographic step in Molecular Genetic » —

Réactifs
IBF

For France : **Pointet Girard** Département Réactifs IBF, 35, avenue Jean-Jaurès - 92390 Villeneuve-la-Garenne.

GUIDE TO AUTHORS

Authors should be aware of the diversity of *Nature's* readership and should strive to be as widely understood as possible.

Review articles should be accessible to the whole readership. Most are commissioned, but unsolicited reviews are welcome (in which case prior consultation with the office is desirable).

Scientific articles are research reports whose conclusions are of general interest or which represent substantial advances of understanding. The text should not exceed 3,000 words and six displayed items (figures plus tables). The article should include an abstract of about 50 words.

Letters to *Nature* are ordinarily 1,000 words long with no more than four displayed items. The first paragraph (not exceeding 150 words) should say what the letter is about, why the study it reports was undertaken and what the conclusions are.

Matters arising are brief comments (up to 500 words) on articles and letters recently published in *Nature*. The originator of a Matters Arising contribution should initially send his manuscript to the author of the original paper and both parties should, wherever possible, agree on what is to be submitted.

Manuscripts may be submitted either to London or Washington (decisions being made only in London). Manuscripts should be typed (double spacing) on one side of the paper only. Three copies are required, each accompanied by copies of lettered artwork. No title should exceed 80 characters in length. Reference lists, figure legends, etc. should be on separate sheets, all of which should be numbered. Abbreviations, symbols, units, etc. should be identified on one copy of the manuscript at their first appearance.

References should appear sequentially indicated by superscripts in the text and should be abbreviated according to the *World List of Scientific Periodicals*, fourth edition (Butterworth 1963-65). The first and last page numbers of each reference should be cited. References to books should clearly indicate the publisher and the date and place of publication. Unpublished articles should not be formally referred to unless accepted or submitted for publication, but may be mentioned in the text.

Each piece of artwork should be clearly marked with the author's name and the figure number. Original artwork should be unlettered. Suggestions for cover illustrations are welcome. Original artwork (and one copy of the manuscript) will be returned when manuscripts cannot be published.

Requests for permission to reproduce material from Nature should be accompanied by a self-addressed (and, in the case of the UK and USA, stamped) envelope.

"Our Vega synthesizer has become an extra pair of hands.

After set up, the syntheses of our oligonucleotides are done reliably 24 hours a day."

Steve Pulford,
Research
Associate,
Genex
Corporation

Genex is just one of over 60 organizations using Vega automated synthesizer equipment to increase productivity and reduce expenses. If you're doing nucleic acid research, or peptide research, or both, Vega has a synthesizer that will meet your scale and budget requirements.

The Coder™

Vega's polynucleotide synthesizer offers the ultimate in flexibility. You can use our synthetic program supplied on floppy disc, or you can program whatever additional custom methodologies you need. Proven coupling efficiency, low operating costs and variable volume capacity are among the reasons genetic researchers are using The Coder™ Model 280.

The Coupler™

Vega's peptide synthesizers are the most economical, totally automated instruments available in the

field. Sized to meet research or production requirements, The Coupler™ Model 250C or The Coupler™ Model 296 will accommodate one gram to 500 grams of resin. Through microprocessor control, the equipment automatically performs all of the washing, deblocking, neutralization and coupling steps required for addition of each amino acid to the peptide chain.

The Coder™ and The Coupler™ Combined

With the new Motorola microprocessor, you can synthesize polynucleotides and peptides simultaneously.

For maximum production capability and cost efficiency, you can operate up to four chemistry modules with one microprocessor. These modules may be all Coders™, all Couplers™, or any combination of models.

Compare The Coder™ and The Coupler™ to other synthesizers available, and you'll see why Genex and more than 60 others have selected Vega equipment. Tomorrow's generation of synthesizers is here today at Vega Biochemicals.

Call 1-800-528-4882 toll free for more information.

Each piece of artwork should be clearly marked with the author's name and the figure number. Original artwork should be unlettered. Suggestions for cover illustrations are welcome. Original artwork (and one copy of the manuscript) will be returned when manuscripts cannot be published.

New

Nunc-TSP

Screening System

- Time saving
- Early screening
- No effect on cells
- Easy to handle
- Tests can be repeated under identical conditions
- No sizeable investments

The Nunc-TSP is a plate with 96 pins that have been specially produced in order to ensure high and uniform binding of polar and charged molecules (e.g. proteins).

The Nunc-TSP is based on the EIA principle, but unlike previous systems it functions »in situ«, i. e. medium is not removed from the cultured hybridoma cells. This means that the testing procedure will have no influence on the cell growth and that it can be repeated under identical conditions without changing the composition of the medium.

The Nunc-TSP provides easy handling with no or few pipetting operations, and at the same time it ensures simultaneous starting and stopping of the reactions in all 96 wells of the microtest plate.

The Nunc-TSP is used together with Nunc microtest plates. A semi-automatic or fully automatic washer are available. If only small numbers of Nunc-TSP are used, the washing can be done in the carrier-plate.

Benzodiazepine receptor preparation

Amersham's benzodiazepine receptor preparation,* N.230, provides a specific, sensitive and rapid means for the determination of benzodiazepines and their active metabolites in biological fluids.

Lorazepam, N.232

[N-methyl-³H]
Flunitrazepam,
TRK. 590

B-[6-³H] Carboline-3-carboxylic
acid, ethyl ester, TRK.664
(non-radioactive compound, N.231)

- The receptor assay protocol is based on the competition between [N-methyl-³H] flunitrazepam and biologically active benzodiazepines.
- The sensitivity of the assay is demonstrated by the standard curve shown above constructed using lorazepam, N.232.
- The specificity of the receptor preparation is similar to that of fresh membrane-bound rat brain benzodiazepine receptors.

Please contact Amersham or your local distributor for further details.

*Manufactured for Amersham International by A/S Ferrosan, Denmark.

GUIDE TO AUTHORS

Authors should be aware of the diversity of *Nature*'s readership and should strive to be as widely understood as possible.

Review articles should be accessible to the whole readership. Most are commissioned, but unsolicited reviews are welcome (in which case prior consultation with the office is desirable).

Scientific articles are research reports whose conclusions are of general interest or which represent substantial advances of understanding. The text should not exceed 3,000 words and six displayed items (figures plus tables). The article should include an abstract of about 50 words.

Letters to *Nature* are ordinarily 1,000 words long with no more than four displayed items. The first paragraph (not exceeding 150 words) should say what the letter is about, why the study it reports was undertaken and what the conclusions are.

Matters arising are brief comments (up to 500 words) on articles and letters recently published in *Nature*. The originator of a Matters Arising contribution should initially send his manuscript to the author of the original paper and both parties should, wherever possible, agree on what is to be submitted.

Manuscripts may be submitted either to London or Washington (decisions being made only in London). Manuscripts should be typed (double spacing) on one side of the paper only. Three copies are required, each accompanied by copies of lettered artwork. No title should exceed 80 characters in length. Reference lists, figure legends, etc. should be on separate sheets, all of which should be numbered. Abbreviations, symbols, units, etc. should be identified on one copy of the manuscript at their first appearance.

References should appear sequentially indicated by superscripts in the text and should be abbreviated according to the *World List of Scientific Periodicals*, fourth edition (Butterworth 1963-65). The first and last page numbers of each reference should be cited. References to books should clearly indicate the publisher and the date and place of publication. Unpublished articles should not be formally referred to unless accepted or submitted for publication, but may be mentioned in the text.

Each piece of artwork should be clearly marked with the author's name and the figure number. Original artwork should be unlettered. Suggestions for cover illustrations are welcome. Original artwork (and one copy of the manuscript) will be returned when manuscripts cannot be published.

Requests for permission to reproduce material from Nature should be accompanied by a self-addressed (and, in the case of the UK and USA, stamped) envelope.

Nature in Poland

Readers wishing to subscribe to a weekly copy of *Nature* on behalf of a colleague in Poland (where hard currency is scarce) should send a cheque for £50 (or the equivalent in any currency), accompanied by their name and address and that of the proposed recipient, to the *Nature* office in London or New York (see addresses opposite page 765). For further details, readers are referred to *Nature* 3 June, p.354.

Too-easy-to-lose Wall Street blues

Stocks have been rallying and rates of both interest and inflation falling. Is the beginning of the end of the recession therefore in sight or is there more misery to come?

Does the recent excitement on Wall Street and the rallies that have followed on other stock exchanges, mean that the long recession is coming to an end? It is natural that people should now be asking this hopeful question just as it is natural that a man lost in a desert should mistake refraction of light in the hot air near the ground for a pool of water. For if the people who make their livings by buying and selling stocks in commercial corporations now think it worthwhile to pay more for the commodities in which they trade, does that not imply that the outlook for US industry has improved? And does it not follow that industrial economies elsewhere will soon be on the mend? Unfortunately these conclusions, welcome though they would be, are unwarrantable. This is why.

Last week's rally on the stock exchanges followed from two significant developments in the United States — a modest but steady decline in the prevailing high interest rates and the government's success in persuading Congress, on the eve of its summer holidays, to enact a package of tax increases that will bring in an extra \$98,300 million over the next three years. If the financial community had waited a few days, it would no doubt have been further cheered to know that the annual rate of inflation in the United States has now fallen to 6.7 per cent. While each of these developments is a sign of progress in the right direction, neither of them implies that the end of the recession is at hand.

The decline of interest rates to below 14 per cent (when banks lend to each other or when people lend to the government) may save many industrial corporations from bankruptcy, but there is as yet no sign that corporations will seize this opportunity to invest in new plants and equipment. Why should they when they have to pay more than 17 per cent for the funds they borrow from the money market and the bank? A decline of interest rates is rather a sign that industry has virtually dropped out of the competition for people's savings, leaving the government as the only borrower of significance. This development is therefore more a sign that the recession has begun to bite than the promise that it is coming to an end.

On present form this will remain the case for some time to come. The package of tax increases half-heartedly proposed by the government and reluctantly swallowed by Congress will not do much to help. The government's deficit for the present financial year (which ends on 30 September) will be untouched at \$110,000 million or more. The tax increases now enacted will be effective only after 1 October, and are smaller than last year's tax reductions, also then coming into effect, and will not in themselves prevent the government's deficit actually increasing in future years. The hopeful sign and the only reason why Wall Street is excited is merely that the Reagan Administration appears at last to have recognized that it cannot run deficits on this scale without also running the economy into the ground. That a Republican administration should so lightly have thrown to the wind the traditional (and old-fashioned) Republican preoccupation with balanced budgets, remains a puzzle, while Mr Reagan's support for the proposed constitutional amendment that would compel future governments to balance their books is about as easily understood as a burglar's espousal of the calls of law and order.

The chances now are high that when the November elections are safely past, the President will make another attempt to behave as he says he should and will ask Congress to agree to a more substantial reduction of the social expenditure to which it has committed him. That will be a more bloody battle than that now won. The outcome cannot be foretold, but success will mean further misery for the growing army of the unemployed, now 9.7 per cent of the working population.

Meanwhile, there is precious little evidence that the transformation of the US industry has gone far enough to provide a foundation for future prosperity. As in most of Western Europe the privations of the recession have not yet made conventional manufacturing industry competitive with similar industries elsewhere, principally in Japan. Indeed, in the manufacture of steel and motor cars for example, the chief preoccupation is still to keep some semblance of these industries alive when there is no reason to suppose that they have an important place in the world. The time to celebrate the impending end of the recession will be when tangible signs of new industries emerging and of improved productivity in conventional industries are plain for all to see.

A very different game

Can French success in boosting nuclear and space technology be repeated in electronics?

A few weeks ago, the French government announced that it was to invest FF140,000 million (£12,000 million) in the French electronics industry over the next three to five years — an apparently vast sum by all measures (see *Nature* 5 August, p.504). But now the dust is beginning to settle, it seems the amount of new government cash may not be so great. Some FF 90,000 million of the total was already due to be invested by the industry itself; and of the remaining FF50,000 million promised by the government (none of which has yet materialized) most can be accounted for by money already budgeted by the industry to be raised from the banks and other sources now nationalized.

So what is the great French electronics plan really all about? Central planning, it seems, despite President Mitterrand's insistence that the leadership of the nationalized industries would be free to manage their industries as they wished. What the President failed to emphasize was that the leadership would be chosen by the government.

So, for example, when the president of the newly-nationalized giant chemicals corporation, Rhône-Poulenc, felt obliged to resign recently (in protest against the "inconsistency" of government policy for his industry), the matter was dismissed by research and industry minister Jean-Pierre Chevènement in revealing terms. The state was in need of "good servants", he said. Jean Gandois, the resigning president, replied that he had found himself to be a "hostage" of the government.

With the leadership of much of industry in its pocket, therefore, the government must now manage industry — something that the present British government would consider to be a logical impossibility. In France, the division between government and industry is not so sharp; the leaders of both

sectors tend to come through the same somewhat military system of education — the *grandes écoles* — and interchange and interaction between civil service and industry is traditionally much stronger in France than in Britain.

Thus the change under Mitterrand is not so much a change of principle as of degree. There is, however, in this socialist government, an increased tendency to make appointments on political and ideological grounds, and voices in the electronics industry in particular are beginning to question the experience and suitability of some of their new leaders.

Moreover, the government has selected electronics to be the centrepiece of its five-year plan for the regeneration of French industry, putting the field on a par with nuclear power and space technology — the other areas very successfully championed by past French governments. But electronics is a very different game. In nuclear power, and in space, there is essentially one customer — the government — at least in the first decade or so while the business is being established. Here, a simple military regimentation of the industry towards well-defined goals will work, as all levers are in the government's hands. But in consumer electronics, for example, there are millions of customers, and there must be flexibility in response to changes in demand and competition. Even the products may change radically. It is doubtful if even the French government machine will be supple enough to deal with this by central planning, however complex the plan.

It may be, therefore, that the great government effort on electronics will work only in those areas where electronics is most like nuclear power and space, in having small, well-defined markets with few customers. This would mean that France should be watched now not for its calculators or video recorders, nor for its consumer products, but for what is called "professional electronics" — defence equipment, where there is a large French and foreign market, electronics for broadcasting and so on.

However, there is one clear thing that a great centralized plan for electronics could do. The importance of components (chips) and of software is increasing in all parts of the industry as one influential (and sceptical) director in the French electronics industry, M. Pierre Aigrain, points out. If the government can put these crucial parts of the French electronics house in order, and bring them to bear on the rest of the industry, whatever can be done by central control will have been done. Other, that is, than providing some real (rather than promised) investment.

Father William's jaw

The cost of caring for old people in the United States will grow dramatically if nothing is done.

Last week's \$98,300 million tax bill, passed by the US Congress with such fanfare, held portents of future problems for old people in the United States, for it showed the tremendous pressures that have mounted on the cost of caring for them. And while scientists like to think that the orderly world of their laboratories is far removed from political fights over Medicare and Medicaid, the research priorities of biomedical scientists in the next few years could have an impact on future costs of caring for the elderly, not to mention an impact on their well-being. US biomedical research and social policy, then, are linked.

The new law, for example, will reduce the chief health programme for the elderly, Medicare, which now costs \$53,000 million, by \$13,300 million over the next three years and increase the costs paid directly by old people by, for example, making elderly hospital patients bear some of the costs of radiology and pathology.

The move to reduce costs collides head-on with the increasing number of old people in the US population, whose government-supported health care will have to be paid from the taxes of a relatively smaller group of younger, working people (*Nature* 26 August, p.779). The resulting battle will make this year's skirmishes between the "gray lobby" seeking to retain federal

benefits, and Reagan-inspired budget cutters, look almost trivial.

Matters are not helped by the fact that the present system of Medicare and Medicaid encourages doctors to treat hospitalized patients with acute problems while most custodial care, long term care and outpatient care, is not covered.

The system reinforces what Robert N. Butler, the outgoing director of the National Institute on Aging, calls "Peter Pan Medicine": a young or middle-aged person with an acute problem but good chances of recovery is a subject of interest and is given the maximum care at no extra cost, while an older person, whose health problems are limited to outpatient visits, is not allowed to charge to the government the cost of medication and, if in hospital, is considered a less interesting case and so gets relatively little attention.

Even worse off are those in nursing homes, for long the step-children of the health care system. Federal insurance does not extend to the costs of nursing homes and Medicare pays only for those who have entered a home after an acute illness in hospital, and then only for 100 days. Meanwhile there is no evidence that nursing homes are any good, having been divorced from the mainstream of research, teaching hospitals and medical practice for so long. There are no teaching nursing homes, although the National Institute on Aging plans to try some, and there is currently only one registered nurse for every 68 residents in the country's 60,000 nursing homes. Many do not even have a regular doctor available.

Demographics will only make this worse. There were 1.3 million people in nursing homes in 1978; there will be 2.1 million in the year 2003. In the present political climate it is impossible to believe that federal benefits will be extended to include long-term care. But could not the need for long-term care be reduced by a better understanding of its medical causes? Why are people in nursing homes to begin with? Could science enable nursing homes to go the way of the TB sanatorium?

Most people enter long term care because they are senile, many of them suffering from Alzheimer's disease. Here, at least, recent progress in understanding the disease at the cellular level and its possible association with slow viruses holds out some hope. Another major reason people are sent to nursing homes is urinary incontinence, about which little is known. Next come infectious diseases, notably pneumonia and influenza, but also herpes zoster (shingles), tetanus and even tuberculosis and chickenpox, causing one in four deaths of elderly people. Here, a better understanding of the effects of ageing on the immune system could help.

Finally, there are bone fractures, encouraged by osteoporosis which could perhaps be minimized by better care in middle age and early old age, perhaps through fluoride and calcium supplements, treatments with oestrogen, progesterone, and vitamin D, and even exercise. Butler goes farther to say that biomarkers, "clocks" to detect how far organ and bodily functions have aged, may make it possible to run short clinical trials, obviating the need to wait many years for a result. This could make possible more direct study of the ageing process, and whether factors such as early diet are linked to old-age symptoms.

These are long-term goals but not far fetched ones considering the high potential social payoff. The "gray lobby", caught in yearly battles, seems unlikely to make a high priority of broad-based biomedical research, with its ifs and buts and necessarily long-term payoffs. It is the research community who hold the keys to the elderly's best hopes 20 years hence and who should take the initiative.

Only the scientists can perhaps ensure that we approach the ideal of a healthy older person, who is not senile, whose bones are not too frail, who is not humiliated by incontinence and who does not die of diseases a child would shake off.

The elderly might even come to resemble Lewis Carroll's Old Father William whose muscular jaws and hearty eating were attributed to the arguing he did as a youngster. Old Father William could stand on his head, somersault backwards, eat a goose, bones and beak, and kick his son downstairs. One thinks of him as a shrewd old fellow, who surely did not cost the state any money.

Pipeline embargo in new jeopardy

Soviet Union's technology could adapt

President Reagan's ploy to stop or delay the supply of Siberian natural gas to Western Europe may all be in vain — because of two simple technical options open to the Soviets.

Reagan's tactics have been to urge European steel manufacturers — particularly West Germany — to stop supplies of the large-diameter (1.42m) steel pipe needed for the line; and to forbid General Electric and other American suppliers from shipping key parts (for example turbine blades) to Western manufacturers making the gas turbines and compressors needed to pump the gas.

But the Soviet Union is experimenting with increasing the pressure of gas in the line from its nominal 75 atmospheres to 100 or even 120 atmospheres. At 100 atmospheres, the pipeline could be built with only two parallel pipes (the current design has three) and yet carry the same net flow of gas (40,000 million standard m³ a year). At 120 atmospheres, only one pipe would be needed, according to official reports in the newspaper *Pravda*. This would reduce the steel requirements for the line to within the capacity of Soviet industry (although the higher pressure pipes would have to be reinforced), and it would also drastically reduce the cost.

Another neglected fact is that the design capacity of the line is in excess of the contracts for gas so far signed in Europe. Since the power required to pump gas down a pipeline rises more than linearly with the rate of gas pumped, it would be possible for the Soviets to pump the contracted gas with many fewer than the 125 gas turbines of 25 MW currently on order in Europe. The 125 turbines are only necessary to pump the full design flow rate.

Exactly how many turbines the Soviet Union would need to be in place by 1984 — when the line is supposed to come on stream — depends on the detailed characteristics of the line. However, the plan is to supply just 15,000 million m³ at that date — under 40 per cent of capacity. It was never envisaged that the line would be pumping its full capacity before 1987.

In fact, according to British pipeline engineers, it would be presumptuous to assume that the Soviets would need as much as 15/40 of design pumping power by 1984, that is 47 or so 25-MW turbine and compressor sets.

It happens that there are parts available in Europe to supply 23 such sets to the Soviet Union, six at John Brown in

Scotland and the rest in France and Italy. That would leave the Soviet Union with at most 24 sets to supply from its own industry in Leningrad, as opposed to the 102 apparent from the design. According to British turbine manufacturers, the General Electric turbines are not particularly sophisticated technology — they are based on 1950s steam turbine design. The obstacle to their manufacture in the Soviet Union is primarily a matter of industrial capacity.

At present, the Soviet Union has no such capacity for 25-MW sets, but West European engineers are convinced that a working prototype is now under test in Leningrad. According to Soviet sources this prototype is "even more efficient" than the General Electric sets it is designed to replace. Whether the Leningrad works could supply 24 of these sets in working order by 1984 is open to question, but the target is a good deal more realistic than the 102 that the Reagan embargo apparently implied.

Another option open to the Soviet Union is to divert 10-MW set production, for which it has capacity, from the six national pipelines under construction. And

in Europe, the French company Alsthom-Atlantique has the capacity to build complete turbines (albeit under licence from General Electric, and so in defiance of the Reagan embargo and so in risk of penalties in America).

Thus it seems entirely conceivable that one way or another the Soviet Union will meet its 1984 deadline — and that it could develop the capacity to bring the line up to full flow by 1987, as Soviet sources continually affirm.

The pipeline design requires three 4,500 km strings to bring the gas from Siberia to the Western border of the Soviet Union. So far, 2,700 km of pipe have been delivered to the pipeline builders, according to the Soviet news agency Tass. Some 500 km of pipe have been welded into a single line, says Tass, and by mid-August 250 km had been laid in place.

Pipe laying equipment which was to have been supplied by the American Caterpillar company is also embargoed, but a new Soviet-designed pipe-layer is now under test, says Tass. The Japanese company Komatsu is also substituting for Caterpillar equipment, according to the news agency.

Robert Walgate and Vera Rich

EPA holds out against lead

Washington

The US Environmental Protection Agency (EPA) stuck to its guns last week and issued a regulation tightening limits on lead in gasoline, despite pressure from the Office of Management and Budget (OMB) to back off.

The new rule, to take effect on 1 November, limits the lead content of leaded gasoline to 1.1 grammes per gallon. EPA estimates that after eight years, airborne lead concentrations will be 31 per cent lower than they would be without the new rule.

Under current regulations, refiners are allowed to average the lead content of all their gasoline, both leaded and unleaded; that pool average must not exceed 0.5 grammes per gallon. But as a result, refiners have been increasing the lead content of leaded fuel (which cannot be used in new cars with catalytic converters) as demand for it drops off. Adding lead is the cheapest way of increasing octane ratings, and EPA has found refiners using as much as 2 grammes of lead per gallon.

Earlier this year, EPA had proposed relaxing the lead regulations. This was done at the bidding of Vice President George Bush's task force on regulation. But in the face of a storm of protest — and convincing evidence that reductions to date in airborne lead have brought about real reductions in blood-levels — EPA went back to the drawing board.

By the beginning of August, EPA had

completed its about face, and in an apparent attempt to out-flank OMB, leaked its new, tougher proposal to the *New York Times*. OMB nonetheless responded by requesting EPA to reconsider the proposed 1.1 gramme limit but EPA has held its ground.

OMB did get its way, however, over the issue of the so-called small refiners.

Current regulations grant an exemption for refiners who produce less than 50,000 barrels per day; they are allowed to add from 0.8 to 2.65 grammes of lead per gallon, according to their scale of production. The new rules will narrow the exemption, reserving the "small refiner" designation for producers of less than 10,000 barrels a day who were in business before October 1976. According to EPA, this will leave only 74 companies in this category, about half the current number. They will be allowed to add up to 2.5

grammes per gallon. The losers will be the "blenders", companies that jumped into the business in the past few years to take advantage of the small-refiner loophole. They buy cheap gasoline, add lead to boost the octane, then resell it. That practice should be largely halted by the new rules.

Environmental groups are generally pleased with the new rules. The lead industry, predictably, is not. In a letter to the *New York Times* last week, Dr Jerome Cole, vice-president of the International Lead Zinc Research Organization argued that the new regulations will cost the public "millions of barrels of crude oil that lead in gasoline saves while adding billions of dollars to the US balance of payments deficit."

Stephen Budiansky

Affirmative action employer

The launch of the Soyuz-T, with a three person crew including female cosmonaut Svetlana Savitskaya, coincided neatly with the closing of Unispace-82 in Vienna and upstaged the US contribution to equal opportunities in space, the visit to the conference of Dr Anna Fisher, astronaut in training. Miss Savitskaya's visit to Salyut-7, however, should not be viewed simply as a publicity gimmick, nor an attempt to scoop the launch of Dr Sally Ride aboard the Shuttle next spring. The fact that there were female candidates training at the Gagarin space centre was announced some weeks ago. It would seem that, as far as the space planners were concerned, the launching of a woman was the next routine step.

Soviet space policy is strongly committed to the construction of large space stations,

Savitskaya and crew-mates

aboard which women would serve as scientists. ("And, of course, stewardesses", Andrian Nikolaev, the husband of the first Soviet woman cosmonaut Valentina Tereshkova, once added.) Studies of the effect of spaceflight on the female organism are an obvious prerequisite of such a programme. Yet, since Tereshkova's solo flight in 1963, no woman has been placed in orbit. The reason appears to be partly one of what a Soviet space official delicately called "the amenities". Moreover, the 1961 Soyuz-11 disaster, in which three cosmonauts died due to loss of cabin pressure during re-entry, led to a change in procedure; cosmonauts were to wear spacesuits during the re-entry, which meant that crew size had to be reduced from three to two. It was the introduction of the roomier Soyuz-T transport craft and Salyut-7, that made it possible for the multi-crew spacecraft to have a female visitor.

Israeli science politics

Physicist made Science Minister

Rehovot

Professor Yuval Ne'eman, a well known theoretical physicist and former president of Tel Aviv University has become Israel's first Minister of Science, just five years after turning down the post because he preferred to stay out of politics. Since then, though, Ne'eman has become a fully-fledged politician and now represents the nationalist Tehiya Party in the Knesset. When Tehiya joined the Begin-led coalition government, Ne'eman accepted the position of Minister of Science and Development.

Not all of Ne'eman's academic colleagues are enthusiastic about the notion of a ministry with overall responsibility for science. For one thing, they fear that it might mean an undesirable degree of government control. Ne'eman discounts such fears and claims that there are overwhelming benefits in having science represented at cabinet level. Other ministries already have their own chief scientists and research budgets and Ne'eman sees one of his chief tasks as introducing strong central coordination over these separate activities.

Professor Ne'eman is pleased with what has been achieved by Israeli scientists and technologists, but looks forward to a "quantum leap" in these achievements, in particular supporting the idea of creating "science cities". And he has set a target of \$5,000 million dollars a year for the annual income from exports based on local research — the current level being only \$1,000 million.

Although Ne'eman is clearly putting the emphasis on applied research, he says he will also be fighting to see that pure research gets the funds it deserves. He is particularly interested in creating more national experimental facilities like the Weizmann Institute's nuclear accelerator and the 40-inch telescope at Tel Aviv University. He also hopes to explore the possibility of Israel's becoming involved in further multi-national research bodies. Already Israel is a member of the European Molecular Biology Organization, and other candidates are the European Southern Observatory and the European Space Agency.

Only in the past 15 years, says Ne'eman, has advanced science and technology begun to have a serious impact on Israeli industry. Ne'eman himself can claim much of the credit — during the sixties he was amongst those who persuaded the government to back skill-intensive science-based industry at the expense of the labour-intensive textile industry and in the mid-seventies, as Chief Scientist in the Ministry of Defence, he had a significant impact on the country's military science.

Some Israeli scientists are sceptical about one of Ne'eman's pet projects, how-

ever. He is committed to the plan to build a canal from the Mediterranean to the Dead Sea, which among other things will provide hydroelectric power by utilizing water from the hills around the Dead Sea. Some question the value of spending an estimated \$1,000 million on a project that would only provide a few per cent of Israel's energy requirements. Ne'eman, for long a moving spirit behind the plan, maintains that the energy would be available at crucial times and that the canal

Ne'eman takes science to the cabinet

would provide much-needed cooling water for additional thermal power stations along the route.

Looking forward to his new task, the new minister says he will do his best "not to disconnect" from "real science". "I was serving as a military attaché with the Israeli Embassy in London," he recalls, "when I worked with Murray Gell-Mann on 'The Eightfold Way', the theory that led to the prediction of quarks. And if I was able to combine the purchasing of submarines with the charting of elementary particles then, I don't see why I can't maintain the same duality now."

Nechemia Meyers

US degrees

Doctoral decline

Washington

The number of US citizens who received doctorates in the "hard" science fields in the United States declined steadily during the 1970s (see chart). Some see in this trend a dangerous drift away from basic research as a career priority for young US scientists. David A. Shirley, director of the Lawrence Berkeley Laboratory, considers the figures "poignant" evidence of that US society is steering its young people away from basic science.

Another explanation is the changing environment in US university science departments, and the steady upward trend in salaries offered by industry to graduates who have made the initial four-year invest-

ment in a bachelor's degree in the hard sciences or engineering.

When US university science departments were expanding and funding was ample, a career in science was seen as the direct pursuit of a PhD and a research career on a university faculty. Young people were encouraged to consider this the most promising route — it being also the one their faculty advisers had usually followed.

But now there are few positions available to a young PhD in university departments

The number of doctorates in science and engineering awarded to US citizens by US universities. Figures in parentheses give % decline from 1970 to 1980.

and laboratories, and still fewer with prospects of a permanent university job with tenure. Furthermore, industry pay is better. One recent survey found that industry offers geologists with a master's degree much the same salary (up to \$24,000) as they would command with a PhD as an assistant professor. So increasingly, young US researchers may not see academia as a promising or even stable place to be.

So, should they bother to get a PhD before entering industry? In June 1982, new PhDs in mathematics were offered an average of \$30,000 a year by industry, whereas new bachelors' degree holders in the field were offered, on average, \$9,000 less. Chemical engineers with a PhD were offered on average \$36,000 and again those with bachelors' degrees were offered

\$9,000 less. Since a doctorate takes seven years to earn, and the candidate earns little or no money during that time and must pay for tuition, the \$1,300 reward per year of study for the degree might seem insufficient.

So economics may be reshaping student attitudes away from the traditional career of a PhD and a university post. Of the situation, they may even be thinking, as one manpower specialist said, "why can't I do good work in industry, too?"

Deborah Shapley

Artificial intelligence

Industry beckons students

Pittsburgh

When 1,500 of the hard core among computer adepts converged upon the University of Pittsburgh campus for the National Conference on Artificial Intelligence (AI) recently, the usual talk of knowledge representation, the meaning of contradiction and many dozen other steps on the long road to a computer with human-like reasoning and perception, was supplemented by talk of entrepreneurship and commercialization. This is something new for the infant field of AI, and it has the field's old guard worried.

The change was apparent in both the exhibitors at the meeting and the audience; Dr Roger Schank of Yale University, who is also the founder of Cognitive Systems Inc, a prototype of small entrepreneurial ventures in AI, noted that ten years ago not a single venture capitalist was to be seen at AI meetings. This year, Cognitive Systems was one of several firms showing off specialized information systems for applications such as petroleum exploration, molecular genetics research and financial analysis.

Leading the charge against the new commercialism was Professor Marvin Minsky of the Massachusetts Institute of Technology, the "dean" of AI. "What I don't like about the problems most people work on is that there's too much 'do-goodism' in them," he said. Applications, such as information systems to aid in medical diagnosis or petroleum exploration draw talented people away from work that will do greater good in the long run. Minsky warned that most of the basic research in AI is done by doctoral students who then

go to work for a company, applying the AI expertise of several years ago on some very specific problem, such as signal processing (or, as Schank put it, "expert systems on paint thinners"). In so doing, Minsky said, "they rob the world of their intelligence".

The lure of industry is also attracting established university researchers in AI, just as it has in other engineering fields. A substantial number of people moving into industry are at the middle level, according to Professor Allen Newell of Carnegie-Mellon University. Newell said these are the researchers who would otherwise just be taking over their own research programmes at universities, and "we're really going to feel that loss".

According to Newell, universities should be made more competitive, both in salaries and research facilities. The average university researcher, he said, receives only one-half to two-thirds of the research support that an industry researcher receives.

To be sure, what is now happening to AI is no different from what has happened for years to computer science and engineering in general. AI, however, may be much more vulnerable. It is still a very young and speculative field, and thus pressures from industry for quick pay-backs are at once stronger and more acutely felt. The result, said Minsky, is that in the entire field there are less than 100 people who have a "license to kill" in having the freedom to spend five or ten years on a single project.

And Minsky offered a history lesson to those who expect quicker results. "It was 300 years from Galileo to Einstein," he said. "What could those fellows have been doing?"

Stephen Budiansky

University woos Oak Ridge laboratory

Last May, when the Union Carbide Corporation announced it would not renew the contract it has long held with the government to manage the Oak Ridge National Laboratory (ORNL) and three related atomic facilities, most observers expected some other corporation to take over (*Nature* 27 May, p.255).

The bidding has barely begun; indeed the US Department of Energy is only just asking all who are interested to make themselves known. Surprisingly, the local University of Tennessee at Knoxville, looks the most serious contender.

L. Evans Roth, the university's Vice Chancellor for Graduate Education, argues that the ORNL and the university are already intertwined, with ORNL scientists teaching at the university and the university programmes under way at the lab. "We already have a marriage without the contract", Roth says.

There is little doubt that acquiring the highly prestigious multi-disciplinary lab-

oratory would be a feather in the university's cap, and to that end it has a task force studying the shape of a management contract, with separate committees on administration, scientific-technical matters, and faculty liaison. Roth and other officials have toured the other national laboratories to look at other university/laboratory relationships, and Glenn Seaborg, the Nobel Prize winner and former atomic energy chief, has visited Knoxville to proffer advice.

Oak Ridge, on the other hand, may have mixed feelings about a union with the University of Tennessee — a state institution with 45,000 students and little experience in managing a giant research enterprise. Now under fire from many in Washington who are questioning the value of places like ORNL, the laboratory might be better served by a more experienced partner. The final decision may depend on what other suitors emerge in the months ahead.

Deborah Shapley

US medical care

Hospices gain

Washington

What could be a major shift in the pattern of US health care lies nearly hidden in the big tax bill Congress passed on 19 August. This is a feature allowing the federal government to pay for hospice care, that is, care of terminally ill people who have chosen not to have extreme life-prolonging measures and want to "die with dignity". Some 95 per cent of US hospice patients have cancer, and an estimated half of them are over 65.

The advent of what amounts to complete federal insurance for hospice care is sure to swell the ranks of those who chose it. Indeed, because this is a budget cutting, cost-saving year for US domestic programmes, the congressmen voted for it because of claims that it would encourage more people to use hospices, relieving pressure on acute care hospitals.

Until now, the estimated 36,000 people receiving hospice care in the United States have had to pay for many of the costs themselves, or have their families pay. Of the estimated 360,000 deaths from cancer per year in the United States, only 10 per cent are now in hospice programmes. So the potential growth of hospice usage is enormous.

According to figures provided by the Congressional Budget Office that Congress relied on heavily in its decision, this extension of Medicare benefits would cost the programme an additional \$1 million per year in the first two years. Afterwards, however, the numbers of people choosing hospices over hospitals would save \$16 million in fiscal 1985 and \$40 million in fiscal 1986. The National Hospice Organization says the cost of home hospice care is up to \$100 a day, compared with \$600 for full hospital care.

The measure's successful passage, despite opposition from the Administration, the American Medical Association, the American Hospital Association, and the Blue Cross Association, has been eclipsed by the larger fight over the tax bill.

The bill has been a focal point for national discussion of how to narrow the federal deficit and give the business community confidence in a US economic recovery. One House staffer deeply involved in the legislation noted that in normal times, something like the hospice measure would have made a big splash at the time it passed. Instead it has barely been reported, having arrived in the final bill by a strange parliamentary route.

In the house the most active proponent was Leon Panetta (Democrat, California), while Senator John Heinz (Republican, Pennsylvania) is responsible for having the Senate version included in the midst of that body's marathon debate on the overall tax bill.

Deborah Shapely

Bankruptcy for interferon firm

Washington

While Southern Biotech Inc., a Tampa, Florida, biotechnology firm that was forced to file for bankruptcy on 28 May, continues to negotiate with its creditors a plan to become solvent again, the US Food and Drug Administration has approved the company's first interferon product for clinical trials.

Approval came on 16 August for US trials of an interferon preparation of possible benefit to lymphoma patients. Although founded and promoted on the basis of its possible interferon sales, the company had not previously been able to market any in the United States, and a 50,000-million unit inventory of alpha-interferon remains unsold.

To facilitate its product reaching doctors in the Florida area, says Daphne B. Floyd, the company's vice-president for marketing, she has helped start a new organization, the Interferon Foundation of Florida, to help tell cancer patients and doctors about interferon. Southern Biotech has donated enough of the newly approved product to the foundation to treat 20 patients.

The company was formed in 1979 by former physician, John Kilgore, who sought to graft an interferon products business using genetic engineering onto a successful blood plasma business. But various deals, including one with Key Energy Enterprises of Tampa, apparently drained the company of cash. Hopes of an innovative research programme under William E. Stewart II, formerly of Memorial Sloan-Kettering Cancer Center, were dashed when Stewart, who was listed

as director of research at the time of the 18 August 1981 stock offering, was fired in September. The prospectus envisaged 17 doctoral-level scientists and a support staff of 34. At present, the scientific staff numbers 3, says Floyd.

However, the company continues to sell its blood plasmas in the United States, while a subsidiary, Southern Biotech Caribbean, located in Kingston, Jamaica, sells its interferon products locally and in West Germany.

Southern Biotech currently has applications for two other interferon products, one for treating breast carcinomas and the other for herpes, filed with FDA, says Floyd.

Deborah Shapely

Spruce bark beetle

Peril imported

Despite stringent import controls which demand the stripping and spraying of imported conifers, the great spruce bark beetle (*Dendroctonus micans*) has found its way into British woodland.

Forestry Commission entomologists have identified the beetle on a private estate near Ludlow in Shropshire and the commission has implemented a monitoring programme using helicopters and foot patrols to survey the area within a 50 mile radius of Ludlow. Other counties affected are Gloucestershire, Hereford, Powys and Glamorgan. The Forestry Commission is optimistic that the pest will remain confined to this area assuming it has not already spread further afield.

Dendroctonus micans attacks and kills

Per cent distribution of UK charities' £64 million expenditure on medical research

The total annual income of the 35 principal UK medical research charities passed £100 million for the first time last year according to figures collated and just released by the Association of Medical Research Charities. Total expenditure was only £3 million less than the £103 million income but only 64 per cent of the expenditure was on "research" (the Spastics Society spent virtually all of its £18 million on such things as housing and care). The diagram shows the major contributors to research spending; none of the "others" spent more than £1 million. For comparison, the Medical Research Council was granted £102 million by Parliament for 1981-82. And in 1981 the National Society for the Prevention of Cruelty to Children collected £6.7 million and the Royal Society for the Prevention of Cruelty to Animals, £7.8 million.

conifer trees, in particular Sitka and Norway spruce, which account for a large part of British woodlands. It is endemic in Northern Europe where forestry management techniques have already been adapted to its presence. The last serious outbreak was in Holland in 1955 but after a four-year programme the beetle was eradicated.

The female great spruce bark beetle attacks spruce 20–25 years old when the bark is thick enough for her to eat out a small protective chamber where she can lay her eggs. Trees which are suffering stress are particularly vulnerable. The 100–300 eggs, laid in two broods, hatch out and the larvae feed on the edge of the chamber before emerging as adults. In serious cases grubs eat out grooves, causing ring bark.

To contain the attacks, affected trees have to be felled and stripped of their bark which is burned on site or sprayed with insecticide. The Forestry Commission has the power to ensure that owners of woodland, both private and public, take action and destroy infested trees.

It is likely that the beetle arrived in Britain in imported timber that was not properly stripped but, because the life cycle of the beetle varies from one to four years, it is impossible to know how long it has been in Britain. What seems certain is that now *Dendroctonus micans* has crossed the Channel it looks like being a pest we will have to learn to live with.

Jane Wynn

East German scientists

Too many now

Science planners in the German Democratic Republic (GDR) have failed to come up with a coherent policy for the division of labour in science, according to leading East German sociologist, Professor Manfred Loetsch. Speaking on Berlin radio, Professor Loetsch claimed that this bad planning was a major cause of the disparity between spending on science and technology and the rise in productivity in the GDR.

Part of the problem, Professor Loetsch suggested, lies in the pay structure of East German science. In general the GDR has a pay policy based on payment by results. But this principle does not apply in science, where there is a fixed pay scale according to the grade of post.

Incentives, however, are not the only requirement for increased scientific productivity. Science in the GDR, said Professor Loetsch, is greatly hampered by the lack of "intermediate personnel". Higher education was greatly expanded during the last decade, but this expansion has not been matched by a parallel growth in the training of technicians. Indeed, the science planners seem to have neglected the need for such auxiliaries, so that whereas the international average for technical research gives six auxiliaries to one scientist, in the GDR the ratio is 0.8 to one. Frequently, Professor Loetsch complained,

Embarrassing admissions cause trouble

Mathematicians and human-rights activists in the West are preparing a petition to appeal for the release of a Soviet colleague, Valerii Senderov, formerly a teacher in one of the Soviet Union's schools for mathematically gifted children. Senderov was arrested in June and is now in pre-trial detention. He will probably be charged under article 70 (anti-Soviet agitation) or article 190/1 (slandering the state).

From the official Soviet point of view, Senderov is a double offender. In 1978 he was a founder member of SMOT, the unauthorized "Inter-professional Free Trade Union" group that has recently faced increasing official hostility (founder member, Albina Vakoreva arrived in Vienna last week, after being forced to emigrate). In addition, Senderov, together with fellow mathematician Boris Kanevskii, has for the past four years been monitoring admissions to Moscow University's faculty of mechanics and mathematics.

Senderov's group claims to have established discrimination against Jews.

In 1979, the team found that of 48 applicants with no Jewish parents or grandparents, who had between them won 26 prizes in the Moscow and All-Union "Olympiads", 38 were admitted to university on the result of their entrance examinations and a further two on appeal. From a group of 40 having at least one Jewish grandparent, who between them gained 48 prizes in the Olympiads, only four were initially admitted and a further two on appeal. The group's most recent report, signed also by mathematicians Naum Meinan and Grigorii Freiman, shows the same pattern for 1980, 41 non-Jewish candidates admitted out of 49, and two "Jewish" candidates out of fifteen.

The arrest of Senderov on 17 June and of Boris Kanevskii only four days later makes a report on this year's entrance examinations, held in July, very unlikely.

Vera Rich

the lack of auxiliaries is justified on ideological grounds, so that, for example, a scientist who complains that shifting stores to the laboratory is not his job will be castigated as an "elitist". Rather than expand unduly the number of graduates, he said, existing graduates should be better deployed. At present a significant proportion of graduates (estimates range from 12 to 20 per cent) are employed in posts for which a university education is not necessary.

Vera Rich

UK academic posts

Muddy waters

Both the British Home Office and the Committee of Vice-Chancellors of British universities have made moves to try and clear up, once and for all, the confusion that persists over the appointment of overseas candidates to UK academic posts. In a recent letter to the vice-chancellors' committee, the Home Office outlined its interpretation of the immigration laws as applied to university staff. And to help universities abide by that interpretation, the vice-chancellors' committee has appointed a special officer to act as an intermediary in disputed cases.

The confusion seems to have arisen because neither universities nor immigration officials have known how to apply British immigration law to overseas students at British universities who later apply for academic posts. British immigration law is against visitors using their foothold in the country to gain permanent residence. But the Home Office also acknowledges the case for employing foreign academics who could make an outstanding contribution.

Hence, determining who should be allowed to stay has often been a lengthy procedure. Universities have taken exception to officials questioning their judgement on who is suitable for a particular job and candidates have been subjected to undue delay before hearing if their applications have been accepted. In some cases, candidates have even been told to go home to their native countries before applying for a work permit.

The Home Office letter signals no change in the law but tries to set out the criteria to be used in deciding whether someone is to get a work permit. There should be evidence, it says, that the person's employment will benefit Britain, either economically or technically, or appreciably enhance Britain's international standing in a particular field of study. The onus is on universities to convince officials that those criteria are met and that no suitable British or EEC national is available for the job.

The vice-chancellors' committee believes that the Home Office letter will help universities by providing guidelines that can be presented before immigration officials.

One further problem for universities, however, could be the Home Office's stipulation that a post must be "justifiable in its own right and not simply in terms of the candidate's abilities". In their current financial straits, not many universities are likely to be creating posts for outstanding individuals. But any that have sufficient cash should be able to hook good overseas academics simply by careful argument with the Home Office, according to David Anderson-Evans, senior administration officer at the vice-chancellors' committee.

CORRESPONDENCE

IQ jump or trend?

SIR — Lynn¹ reported evidence of significantly higher IQ in Japan than in the United States. However, his assertion that Japanese IQ shows a "rising trend" which has resulted in a "growing disparity" is not entirely supported by his data. Statistically, a better fit is obtained by assuming that a discrete jump in IQ has occurred among Japanese born after 1945.

In his analysis, Lynn used the product-moment correlation coefficient to test for trend. This implicitly supposes a linear trend. The least-squares estimate of the trend line is shown in Fig. 1 (dashed line). In fact, Lynn was prepared to discount the 1910 data point as showing the greatest discrepancy and being possibly subject to error. The trend line without the 1910 result is shown as a dotted line. Neither of these lines seems very satisfactory. In the first place, the fitted IQ for 1910 is unreasonably low, being either 98.6 or 94.7 depending upon which line is used. Second, the deviations of the data points around the lines do not show the random pattern which a genuine trend should imply. In

Fig. 1 Mean IQ and year of birth for 23 Japanese cohorts (data from ref. 1). The dashed line is the least-squares regression line fitted to all data points; the dotted line is the least-squares regression line fitted excluding the point for 1910. The unbroken line represents a "jump" model in which IQ is constant prior to and following 1945, but increases by a discrete step during 1945.

particular, for the 1959–69 data (mainly from a single study; see ref. 1), even though the 1959 point is low, there is little sign of a trend. If the trend was as steep as the lines suggest, it should be apparent even over a ten-year time span.

One alternative is that, instead of rising steadily, IQ has risen in a discrete jump around 1945, a time of considerable change in Japan. When the data from all cohorts are considered, the jump model (see Fig. 1) explains 89 per cent of the total variance in IQ while the linear trend accounts only for 61 per cent. If the exclusion of one outlier is permitted (jump model: 1959; trend model: 1910) these figures rise to 95 and 78 per cent, respectively. Thus, the data are much better described by a jump than by a linear trend.

Factors capable of producing a jump in the IQ results may be quite different from those which might cause a trend. In seeking reasons for the apparent rise in Japanese IQ, it may therefore be a mistake to direct too much attention to the latter.

T.B.L. KIRKWOOD

National Institute for Medical Research,
Mill Hill, London, UK

1. Lynn, R. *Nature* 297, 222–223 (1982).

... as I was saying

SIR — On 6 July 1882, I sent you a letter about "The solar commercial cycle" and I promised further elucidation about the "difficulties and objections" to my theory¹. My hope was to answer my detractors who made my theory "the subject of inconsiderate ridicule"². I was prevented from doing so by the events of 13 August 1882. On that day, intending to join my family bathing at Galley Hill beach in Sussex, I chose to descend the right side of the cliff instead of the customary left side. In the cold water I suffered a stroke and my family being on the other side of the cliff were unable to come to my aid; thus I drowned.

One hundred years have passed and all attempts to prove my correlations wrong have failed. The last three to attempt it were obliged to acknowledge that my theory should be considered as a serious hypothesis^{3–5}. After more decades of silence, a few months ago two econometricians tried their new tools and also failed. They reported whimsically: "We conclude that economic activity has an important influence on the Sun. Thus Jevons ... was right but for the wrong reason"⁶.

As the acknowledged father of econometrics⁷, let me clarify the result of their test. The seemingly absurd conclusion is due to the autoregressive mechanism of the econometric model. The sunspot influence enters through the disturbance function. The model acts as a spectral filter on the now strong frequency existing in the disturbance (the sunspot cycle). But, as it is an asymmetric filter, it produces a shift in the phase of the predominant frequency, so that the output phase reading shows up ahead of the input reading.

I also heard lately that the American SMM (Solar Maximum Mission) satellite, kept aloft for the whole year 1980, has proved through accurate instruments that the solar "constant" varies⁸. This is very exciting to me since it confirms the hunch I had in 1878 when I suggested, in your journal, that "solar observatories should be established" high in the mountains to ask the Sun himself "whether he varies or not"⁹.

For one hundred years orthodox science has been insisting that the radiation of the Sun was a "constant". Now all must agree with my 1878 hunch: it is a variable and there are significant changes from day to day, week to week, month to month ... A spectral analysis made of the SMM satellite data suggests periodicities¹⁰, and after a few more years of data, it should be possible to unravel them for forecasting purposes.

The opposition to the factual basis of my theory will crumble some day. Stubborn anomalies cannot be kept in the scientific closet forever, for sooner or later they will out.

Concerning the linking mechanism of my theory, I have very little to add. Linking solar radiation to crop yields was the obvious first choice, but I was never satisfied with it because it did not fit the data well. I have explained how, out of sheer desperation, I thought of the psychological link: "I went so far as to form the rather fanciful hypothesis that the commercial world might be a body so mentally constituted, as Mr John Mills must hold, as to be capable of vibrating in a period

of ten years. ..."¹¹.

I mentioned this idea in all my articles in the form of an inverted rhetorical question. After so much ridicule I had to be careful. My fellow scientists had barely accepted the Darwinian theory that they had vestigial parts of lower animals in their anatomy, but my fellow economists would never accept the idea that "*Homo oeconomicus*" might not have a perfectly rational psychology and is therefore somehow at the mercy of cosmic waves.

At the end of one of my articles in your esteemed journal, I forecast that the solar constant measurement was so crucial to business that, in the future, it would be "the most important news" in the daily paper¹². Living in the Victorian era, I could only insinuate my real thoughts. It is obvious that I was not referring to the effect of these daily fluctuations on crop yields but in a direct action on the solar waves on the psychological "constant" of the population. But now, after the exciting discoveries of the SMM satellite, anybody, by reading my work carefully, can get the full extent of my intuition.

A time will come when the economists will achieve the forecasting ability of the meteorologists and the vulgar will refer to us respectfully as the practitioners of the "dismal" science, the science of calculating "*dies mali*" to advise the politician and businessman properly, not so much what to do but when to do it.

Weapons treaties

SIR — Alastair Hay (*Nature* 8 July, p.205) confuses the international treaties on chemical and biological weapons.

The 1925 Geneva Protocol outlaws the use of both chemical and biological weapons (in practice, first use, because the major parties reserved the right to use them if attacked by them).

The 1972 Biological Weapons Convention — result of a British initiative taken in 1968 — bans the development, production and stockpiling of bacteriological and toxin weapons. The Committee on Disarmament is now discussing the elements of a similar convention banning chemical weapons, in which the UK delegation has made a major contribution with a draft treaty and a working paper on verification.

NEWS AND VIEWS

The *myc* oncogene in man and birds

from Robin Weiss

THE HL-60 cell line derived from a patient with acute promyelocytic leukaemia¹ has proved of great importance for studies of cell differentiation and transformation. The cells in culture resemble promyelocytes but can be induced to differentiate into mature granulocytes² by treatment with dimethyl sulphoxide or retinoids. The phorbol ester tumour promoter, 12-O-tetradecanoyl-phorbol-13-acetate (TPA), on the other hand, causes the cells to differentiate into macrophages³. Given this capacity to differentiate along alternative pathways, HL-60 cells are also valuable for investigating natural factors operating in myeloid cell differentiation⁴ and for delineating cell surface phenotypes during maturation.

As a leukaemic cell line, HL-60 has been examined for the expression of genes which may contribute to its neoplastic phenotype. Weinberg's laboratory⁵ showed that HL-60 DNA sequences transfected into NIH/3T3 cells caused transformation. The transfecting gene remains to be characterized. In the meantime the organization and expression of the *c-myc* gene in HL-60 cells has become a focus of interest.

The *myc* gene was first defined as the unique transforming sequence of MC29 virus and related retroviruses which cause myeloid neoplasms and other types of tumour in chickens⁶. Like other transforming genes ('oncogenes') of retroviruses, DNA sequences homologous to *myc* are found in normal chicken DNA⁶. The viral oncogene, *v-myc*, thus represents a transduced cellular gene, *c-myc*. As *c-myc* sequences have been highly conserved in evolution⁷, a cDNA probe prepared from the avian viral oncogene can be used to detect and clone the homologous gene in human DNA and to study its expression. The *c-myc* gene is expressed in a variety of neoplastic and proliferating normal human cells⁸, but mRNA levels appear to be unusually high in HL-60 cells⁹.

Two laboratories have now shown that *c-myc* DNA sequences are amplified in HL-60 cells. Collins and Groudine¹⁰, using an avian *c-myc* probe, reported in *Nature* a few weeks ago that HL-60 cells have about

16 *c-myc* copies. In this issue of *Nature* (p.61) Dalla Favera *et al.*¹¹, using cloned human *c-myc* probes, confirm this finding and show, moreover, that the leukaemic cells of the patient from whom HL-60 cells are derived were similarly amplified for *c-myc* before the cell line was established in culture. Unfortunately, normal tissue from the patient (long since dead) is no longer available so that it cannot be established whether the *c-myc* gene amplification was constitutional or was the result of somatic mutation in the leukaemia cell clone. Dalla Favera *et al.*¹¹ report that closely related pseudogenes are not amplified, suggesting that amplification might result from selection of *c-myc* function in the leukaemia cells. However, the few other patients with acute myeloid leukaemia that have been studied do not have amplified *c-myc* sequences.

Amplification of other oncogenes has been observed, but in species rather than tumours. Two related cellular genes homologous to sarcoma virus oncogenes, *Ha-ras* and *Ki-ras*, are found in markedly different copy numbers in closely related species¹². For instance, *Mus pahari* contains at least 10 copies of *c-Ha-ras*, whereas other species of mice carry only 1 or 2 copies. The transfecting gene of the human bladder carcinoma line, EJ, is now known to be the *c-Ha-ras* gene¹³, but it is not amplified in the tumour cells. It has not yet been shown whether the transfectable gene in HL-60 cells⁵ is *c-myc*; it may well be a different gene. In chicken bursal lymphomas, although *c-myc* expression is specifically elevated by adjacent provirus integration¹⁴⁻¹⁶, the gene identified by DNA transfection is quite distinct¹⁵. Similarly, the SMS-SB human pre-B leukaemia line expresses high levels of *c-abl*¹⁷, but a different transforming gene has been detected by transfection¹⁸.

The *myc* gene of MC29 is expressed in infected cells as a *gag-myc* 'fusion' protein, p110, translated from a transcript of part of the viral *gag* gene running into

myc. This was first recognized when *gag* antisera precipitated p110 from extracts of transformed cells¹⁹. Following this discovery, several other *v-onc* genes of replication-defective, transforming viruses were also found to be expressed as *gag-onc* fusion proteins. Avian retroviruses of the MC29 group, which carry *v-myc* genes, cause a bewildering variety of neoplasms — myelocytomas, endotheliomas, mesotheliomas, renal and hepatic carcinomas and sarcomas. In some elegant experiments, Graf *et al.*²⁰ showed that MC29 virus transforms both fibroblasts and macrophages in culture, but not erythroblasts, even though p110 is synthesized in infected erythroblasts. Thus, despite the variety of tumours associated with MC29 virus, there is clearly some specificity of target cells for neoplasia following infection. Furthermore, the disease spectrum can be restricted by selective passage *in vivo* of virus extracted from one type of tumour, for example, bone marrow or liver²¹, or by the isolation of *v-myc* deletion mutants *in vitro* that maintain their capacity to transform fibroblasts but are unable to transform macrophages²².

Lymphoid neoplasms are not usually caused by MC29 virus, yet the activation of *c-myc* by provirus integration in the vicinity of the cellular gene is evident in the majority of bursal lymphomas induced by avian leukosis viruses¹⁴⁻¹⁶ and also by the unrelated helper virus of reticuloendotheliosis virus²³. It is puzzling that the elevation of *c-myc* expression by the insertion of viral regulatory sequences appears to be specific to B-cell neoplasms, whereas *v-myc* inserted as part and parcel of the viral genome primarily induces other types of cancer. Hayman *et al.*²⁴, however, have now found that a transforming revertant of one of their *v-myc* deletion mutants causes a high incidence of lymphoid neoplasms with short latency. Tryptic peptide analysis of the *gag-myc* protein of this revertant indicates that the original deletion mutant may have recombined with *c-myc*. The data on deletion mutants and revertants^{22,24}, together with the evidence of selection of disease-specific strains of MC29²¹, suggest that mutations

in the *myc* gene affect its target cell specificity for neoplastic transformation.

What, then, is the function of the p110 protein encoded by the *gag-myc* gene? Unlike several *v-onc* products, p110 has not been shown to have tyrosine phosphokinase activity. Recently, Moelling's²⁵ and Eisenman's²⁶ laboratories have shown both by subcellular fractionation and by immunofluorescence with *gag* antisera that the *gag-myc* protein p110 is located in the nucleus of transformed, non-virus-producing quail cells. Furthermore, purified p110 behaves as a DNA-binding protein²⁵. Since other *gag*-related polypeptides do not migrate to the nucleus or bind to DNA, it is thought that these properties relate to the transforming, *myc*-specific domain of the protein. It will be interesting, therefore, to ascertain whether the *gag-myc* proteins of the MC29 mutants²² bind to chromatin in both fibroblasts (which they transform) and macrophages (which they cannot transform), and the location and function of *c-myc* products, especially of the amplified genes in the HL-60 human leukaemia cells, also merits investigation.

The MC29 *gag-myc* protein is not the only transforming protein to have a nuclear location and DNA-binding properties. Cells transformed by Epstein-Barr virus, adenovirus and papovaviruses all express virus-coded nuclear antigens. As reviewed recently in these columns²⁷, two different viral proteins, SV40 T-antigen and a 58,000 molecular weight protein of adenovirus, both have a high affinity for p53, a host nuclear protein which may play a role in cell proliferation. Could the *myc* product be a transforming protein analogous to T-antigen or p53? □

Streptomyces in the ascendant

from K.F. Chater

DESPITE their manifest importance in antibiotic production, differentiation and soil ecology, mycelial Gram-positive bacteria of the genus *Streptomyces* have been little studied by geneticists and molecular biologists. That this situation is about to change was perhaps the major message conveyed in a recent symposium* in Kyoto on the genetics of these and many other industrial microorganisms. Various novel genetic phenomena in *Streptomyces* were documented, and the availability and use of sophisticated *in vivo* and *in vitro* *Streptomyces* recombination systems, and first steps in understanding both homologous and heterologous expression of *Streptomyces* genes were described.

A + T-rich repeated sequences (up to 12 per cent of the total DNA) are widespread in streptomycetes (R. Kirby *et al.*, University of Capetown). These sequences may have roles both in certain cases of chromosomal and plasmid structural instability, which sometimes involve the complete loss of particular DNA segments such as the tyrosinase gene of *S. reticuli* (H. Schrempf, University of Wurzburg), and in the sporadic extreme tandem amplification of functionally uncharacterized DNA sequences (H. Ono *et al.*, Institute of Microbiology, Zürich; H. Schrempf and see ref. 1). Equally unusual is the discovery of linear *Streptomyces* plasmids which have identical 611 base pair sequences at both ends of the 17 kilobase kb DNA molecules and proteins covalently bound to the 5' termini (H. Hirochika *et al.* Mitsubishi-Kasei Institute of Life Sciences, Tokyo).

Whether it will be possible to exploit these phenomena in the laboratory remains to be seen. Even without them, the *Streptomyces* geneticist has a formidable range of tools, now that endogenous *Streptomyces* DNA cloning is becoming routine. One of the most sophisticated vectors, pIJ61, which is based on the low-copy number plasmid SLP1.2, contains a selectable thiostrepton-resistance marker and a very efficiently expressed neomycin phosphotransferase gene with sites for insertional inactivation (C. Thompson *et al.*, John Innes Institute). pIJ61 was used in what is probably the first cloning of a gene involved in antibiotic production: a *para*-aminobenzoic acid synthetase gene (*pab*) involved in candidicin biosynthesis in *S. griseus* (J. Gil and D. Hopwood, John Innes Institute). Although expressed in several streptomycetes, the cloned *pab* gene was not expressed in *E. coli* unless placed under the control of an *E. coli* promoter by a deletion (it could then 'complement' mutations in both of the

unlinked *pabA* and *pabB* genes of *E. coli*). Several other *Streptomyces* genes failed to be expressed from their own promoters in *E. coli*, including genes for neomycin and viomycin phosphotransferases (D. Hopwood).

Homologous and heterologous gene expression involving *Streptomyces* DNA has been more specifically analysed with a promoter-probe vector also based on SLP1.2 (M. Bibb and S. Cohen, Stanford University). Promoters from *E. coli* (*lacUV5* and *recA*), *Serratia marcescens* (*trp*) and *Bacillus* (*penP*) all allowed the expression in *Streptomyces* of a promoterless chloramphenicol acetyltransferase gene from *E. coli*, as did a number of *Streptomyces* small DNA fragments. On the other hand, the latter fragments did not promote transcription in *E. coli*, their DNA sequences being quite unlike consensus *E. coli* promoters: their only consistent feature was a relative A + T richness (about 60 per cent G + C) in the sixty or so bases upstream of the translated regions, compared with the average G + C content of 70–73 per cent for *Streptomyces* DNA. From these results and other descriptions of the expression of R-primes among various Gram-negative bacteria (B. Holloway, Monash University, Australia) one gains the impression that promoters from low G + C DNA express in organisms with higher G + C DNA more effectively than the reverse. Together with other evidence from Bibb and Cohen that there may be less specificity for ribosomal binding to mRNA in *Streptomyces* than in *Bacillus*, streptomycetes may be uniquely suitable for studies involving heterogenic prokaryotic gene expression. No normal vegetative *Streptomyces* promoters have yet been analysed, though examples of these should soon be available for study, since highly regulated *Streptomyces* β -galactosidase and glycerol degradation genes have now been cloned (T. Eckhardt and L. Fare, Smith, Kline & French Laboratories, Philadelphia; E. Seno *et al.* John Innes Institute). As a result, antibiotic (methylenomycin A) production genes have been cloned in an attachment site deleted ϕ C31 vector carrying a viomycin resistance gene. The cloned genes were recognised because they allowed the vector to integrate into, and disrupt, the homologous genes present in a recipient, giving viomycin resistant, methylenomycin non-producing colonies (K. Chater *et al.*, John Innes Institute).

Among several λ -like *Streptomyces* phage vector systems, the most advanced is based on phage ϕ C31. An early difficulty of rather low transfection frequencies has

Stamp watching and bird collecting

from Robert M. May and Judith May

AESTHETICALLY and philatelically the recent issue of US bird-and-flower stamps is remarkable; each sheet has 50 different 20 cent stamps, depicting the 'state bird' and 'state flower' of each of the 50 states. Scientists may find them additionally interesting for the way they exemplify the peculiarity of our engagement with the order Aves.

Knowing nothing about how the state birds were originally chosen, and given that there are 700 or so species to choose from, one can generate all manner of hypotheses about the diversity of bird species to be found on this set of stamps. The 'null hypothesis' would be that the states chose their birds independently and randomly, in which case we would expect only one or two pairs of states to have chosen the same bird species, and the remaining 48 or 46 states each to have made a unique choice. Of course, this null hypothesis is obviously too simple, as it overlooks biological complications in the relative abundance and geographical distribution of birds, historical and cultural factors in the founding of states, and the particular aesthetic attractions of the favoured species. The stamps in fact show the state birds to be a much less diverse assembly than would be expected on any biological grounds: 7 cardinals (for states from the east coast to Kentucky and Indiana); 6 western meadowlarks (mainly in the north-west); 6 mockingbirds (from southern states); 3 robins; 2 mountain bluebirds; 2 eastern bluebirds; 2 American goldfinches; 2 chickadees; and only 21 singletons.

Over the years, scientists too have shown that they are not immune to avian charms (though the sheer conspicuousness of birds, in comparison with most other vertebrates, undoubtedly accounts for some of this popularity). From Gilbert White's time onwards, a grossly disproportionate number of evolutionary and

ecological studies focus on birds. Many, if not most, of the subject's leading theoreticians in this century — Mayr, Lack, MacArthur and others — have been 'bird people'.

A more general reflection of this fascination is to be found in the hobby/sport/obsession of bird watching, and especially in its strange outgrowth of bird listing. We suppose some people keep life lists of the species of mammals or flowers, though surely not of insects, they have seen (after all, there do exist train listers and plane listers), but we have not met any. Bird listers, however, abound.

From their point of view, North America is a richer place than Britain; around 660 species of birds breed in North America (excluding Greenland, Bermuda and Baja California) and around 710 species are regularly seen, whereas only around 190 species of birds breed in Britain and only around 240 species are regularly seen. This difference in the number of breeding bird species is almost exactly what would be expected from the MacArthur–Wilson species–area relation, $S \sim A^z$, with $z \sim 1/4$; the ratio of the area of North America to that of Britain is roughly 80, whence we would expect roughly a ratio of 3 in the number of species. The agreement is surprising, and must surely be largely coincidental, because the underlying premises from which the species area relation is deduced pertain more to archipelagoes of islands than to large continental masses.

The list of species ever seen in North America totals around 820. In Britain the list numbers around 470, many of which are rare sightings of birds that are lost and do not want to be there. From these numbers it can incidentally be seen that membership in the '600 club' (a life list of 600 North American birds) is a substantial but not unreasonable goal. More arcane are competitions centering on the greatest number of bird species sighted in North America in one year, or simply the greatest number of species seen in any one

day, or even by turning through 360° on one spot. The record for North American bird species seen in one calendar year was until recently held by Scott Robinson, now a Princeton University graduate student, at 657. In 1979, a businessman named Vardaman spent a small fortune in pursuit of the ambition of sighting 700 species in one year. Travelling extensively and advertising widely for people to lead him to rare birds, Vardaman pushed the total number of species he had seen above 690 in the last weeks of December. The magic 700 was to elude him, however. At the year's end Vardaman's record stood at 699. God too is clearly an amateur bird lister.

been overcome by the surprising (and perhaps more widely applicable) finding that small positively charged, DNA-free liposomes greatly stimulate polyethylene glycol-assisted transfection of protoplasts (J. Makins, *et al.*, John Innes Institute).

Cloning systems are especially useful when allied with *in vivo* genetics. This has been made easier in *Streptomyces* by several recent developments. For example, the multicopy 8.9 kb plasmid pIJ101 is a very efficient sex factor which can be transferred into nearly all streptomycetes (D. Hopwood). Other generalized tech-

niques for achieving efficient chromosomal recombination in *Streptomyces* include protoplast fusion² and liposome-mediated transformation³. Perhaps less widely applicable is a system for Ca^{2+} -promoted transformation of competent *S. griseus* cultures by plasmid DNA (Z. Zhuang *et al.*, Institute of Microbiology, Beijing) and the discovery of a (probably narrow host range) temperate phage of *S. fradiae* which exists as a plasmid prophage and is capable of generalized transduction (S. T. Chung, The Upjohn Company, Kalamazoo).

Evidently the immediate future will see the detailed analysis of primary and secondary metabolism and differentiation in *Streptomyces*, together with a widening of our vision of prokaryotic genome structure. Some of the new techniques are sure to influence industrial programmes and may lead to the use of streptomycetes as hosts for foreign DNA expression. □

Seismic triggering and earthquake prediction

from W. Thatcher

WHILE identification of seismic gaps and the determination of earthquake recurrence intervals each provide viable means of assessing long-term earthquake potential¹, at present no comparably reliable methods exist to evaluate intermediate or short-term earthquake risk. Recent work, however, suggests that estimation of short-term risk might be improved by taking into account the potential of aseismic deformation episodes for triggering large earthquakes and incorporating this into a probabilistic assessment of earthquake risk.

The notion that aseismic movements could trigger damaging earthquakes is by no means new. Ever since Richter² pointed out the rather regular east-to-west migration of large shocks on the North Anatolian fault in Turkey, seismologists have been proposing a variety of aseismic processes that might explain this pattern and features similar to it³. What is new, however, is the accumulating evidence that transient and episodic aseismic movements are relatively common rather than extremely rare, and in several well-documented instances it appears that such movements have indeed triggered large earthquakes. The purpose of this article then is two-fold: first, to briefly review the new evidence, and second, to point out how it suggests a more integrated approach to earthquake prediction, one that draws on the evidence of studies of artificially-induced seismicity and that incorporates recently-proposed methods for the probabilistic assessment of earthquake risk⁴.

Although it has been commonly assumed that stress in seismically active regions builds up at uniform rates, geodetic survey measurements provide the evidence that this is not the case. Transient post-seismic movements of considerable size may occur over large areas for several decades after great plate boundary shocks^{5,6}, and episodic strain or elevation changes have been detected in closely monitored seismic gaps in southern California and Japan⁷⁻⁹. Uniform and non-uniform models of stress buildup are contrasted in Figure 1 and it can be seen that episodic movements could trigger a large earthquake to occur sooner than it otherwise might. Figure 2 suggests how episodic deformation could lead to the occurrence of a discernible increase in pre-earthquake minor seismicity.

Both observations and simple triggering models agree that large earthquakes can actually occur as a result of the episodic aseismic stress changes seen in geodetic

survey observations. The best evidence comes from regions where volcanic activity occurs in association with large tectonic earthquakes and triggering is the result of stress changes due to subsurface movements of liquid rock (magma) and associated gases^{10,11}. The relation between volcanism and crustal deformation on the one hand and seismicity and large earthquakes on the other is particularly well seen in Japan's Izu Peninsula¹¹.

There, two episodes of domal uplift have taken place this century (1930-33 and 1975-82), each was centred in a region of

Fig. 1 Idealized modes of stress (or strain) accumulation between consecutive large earthquakes (E). Nonuniform model includes effects of both a steady postseismic decline in rate and the random occurrence of short periods of greater-than-average rates of stress increase (1-4), the last of which triggers seismic failure sooner than would otherwise have been the case (dotted curve). For simplicity the figure assumes that stress levels at any instant are everywhere the same on the eventual rupture surface. Alternatively, it can be considered that the figure shows only the stresses at the eventual earthquake hypocentre, the initiation point of failure.

Quaternary volcanism, involved uplifts of 0.2 m or more, and covered an area about 30 km in diameter. A simple magma-chamber-inflation model explains the uplift quite well¹². Near the periphery of the uplifted regions, three strike-slip earthquakes of about magnitude 7 have occurred (1930, 1978, 1980) and been preceded by one to three years of domal uplift in an adjacent region. In addition, earthquake-swarm activity was particularly marked during 1930-34 and 1975-81 and conspicuously absent during the intervening 40 years.

An inflation model shows¹¹ that shear stress increments of about a bar (0.1 MPa) were generated across the fault planes of each of these three earthquakes, in all cases acting in the correct sense to trigger seismic slippage. Of course, this increase is no more than a few per cent of the stress increment required to cause failure, the majority being supplied by regional tectonic stresses resulting from the collision of the Philippine Sea and Eurasian plates¹³.

However, because the recurrence interval for earthquakes of magnitude 7 on each of these faults is approximately 1,000 years or more¹⁴, these inflation-induced stress changes represent the equivalent of several decades of secular average stress buildup.

Several studies suggest that postseismic transient stress changes trigger notable earthquake activity. Utsu and Shimazaki¹⁵ have shown that in Japan, large intraplate earthquakes occur more frequently during the 10 years after a great underthrust event at the adjacent plate boundary than at other times. Studies of postseismic level changes that followed the great 1946 Nankaido earthquake demonstrate that, in contrast to interseismic secular movements, transient deformation in the several decades since 1946 extended more than 350 km inland from the plate boundary⁶. In addition, Lehner *et al.*¹⁶, following a suggestion by Anderson¹⁷, have shown that observed migrations of great earthquakes along major plate boundaries can reasonably be attributed to gradual lateral diffusion of postseismic stress away from the rupture zones of individual shocks.

Earthquakes induced by reservoir loading provide a further example of seismic triggering consistent with the mechanism sketched in Figure 1. As the graph suggests, episodic stress changes, of which the filling of a reservoir is one example, need not trigger damaging earthquakes, or indeed any earthquakes at all. Should they do so, the triggering stresses need only be a small fraction of the ambient tectonic level. Simpson¹⁸ has shown that discernible increases in post-impoundment seismicity have occurred in only a small proportion of the world's large reservoirs but further suggests that in many instances only very small stress or pore pressure changes were required to induce tectonic earthquakes of magnitude 5 or greater. Earthquakes associated with fluid injection were probably triggered by considerably larger pore pressure changes¹⁹. Swarm activity appears to precede all the well-documented large artificially-induced shocks¹⁸, and the mechanism sketched in Figure 2 may be an appropriate explanation of this activity.

While not being definite indicators of impending earthquakes, the occurrence of episodic deformation can nonetheless be taken as one indication of increased seismic risk, and several studies have suggested how they might be used to assess earthquake hazard. With respect to the strain changes observed in southern California during 1979, Raleigh *et al.*²⁰ draw attention to the non-linear character of the buildup occurring there and suggest that risk be assessed by determining whether the strain increments bring the faults of the San Andreas system closer to failure or tend to

W. Thatcher is with the US Geological Survey, Menlo Park, California 94025. A.G. Lindh, T.C. Hanks and D.J. Andrews are thanked for their helpful discussion of the paper.

① UNIFORM STRAIN BUILDUP

② EPISODIC DEFORMATION

Fig 2 Possible forms of pre-earthquake seismicity

lock them, impeding slippage. They further emphasize the importance of concurrent monitoring of seismicity levels on these faults. In evaluating an earlier episode of straining that may have been related to the southern California uplift⁹, I suggested²¹ that the pattern of movements indicated relative locking of the San Andreas fault but increasing shear stresses on the bounding thrust faults of the Transverse Ranges.

Evaluation of these and other factors, as well as more concentrated monitoring, should provide rational criteria for deciding whether the probability of an earthquake has increased or decreased. Once a deformation episode has been identified, a discernible increase in micro-seismicity would provide one indicator of increased risk. The magnitude and sense of stress or strain change across candidate faults would provide another basis for deciding whether risk level should be raised or lowered. Provided areal and temporal coverage were adequate, such changes could be determined directly from geodetic data, alternatively, as was the case for the Izu Peninsula earthquakes¹¹, model calculations or indirect inferences might suffice. Earthquake focal mechanisms provide a third evaluation criterion: if micro-fault movements are in the sense expected from observed or inferred stress increments, then the probability of a damaging shock should be correspondingly increased. Even at this point, however, a large earthquake remains by no means inevitable and, in this view, no amount of positive evidence will suffice to make it so.

Nonetheless, this monitoring strategy has several advantages. It is straightforward, relies on simple physical concepts, and emphasizes well-proven methods of geodetic surveying and seismic

network operation. An emphasis on identifying episodic crustal movements and their consequences provides a rationale and focus that may be absent in a strictly empirical search for earthquake precursors. Once anomalous movements are detected, follow-up studies can begin immediately and provide risk assessments that can be continuously updated.

The ultimate importance of triggering mechanisms for earthquake prediction depends, of course, on how commonly large earthquakes are caused by detectable episodic or transient stress increases. Although this is not known, in general the probability of triggering would be expected to increase as the frequency and amplitude of episodic strain changes increase. Clearly, as Figure 1 indicates, the fault zone must already be rather close to failure.

Obvious candidates for close attention are identified seismic gaps and faults for which the time since the last large earthquake is comparable to the recurrence interval for such events. Matsuda¹⁴ has identified four such intraplate faults in Japan and refers to them as 'precaution faults'. McCann *et al.*¹ defined category 1 seismic gaps as those likely to rupture in a great earthquake 'within the next decade or few decades', and showed that seven gaps identified by this criterion since the late 1960's have subsequently been filled. From this perspective, the potential importance of triggering can perhaps best be appreciated by noting that, for many such seismic gaps, already documented episodic movements would be the equivalent of a decade or more of secular strain accumulation. □

Synthetase U-turns

from Graham Cowling

Now that the problems of gene sequence and structure are essentially solved, molecular biologists are beginning to tackle the next obstacle to a complete understanding of the translation, transcription and replication processes — the interactions between proteins and nucleic acids. The task is clearly a Herculean one and it is thus encouraging to find that advances have already been made in one area, the mechanism of aminoacyl-tRNA synthetase action.

The aminoacyl-tRNA synthetases are an abundant class of cellular enzymes that assign amino acids to trinucleotide sequences (anticodons) of tRNA. They aminoacylate tRNA in a two-step reaction, first an amino acid is condensed with ATP to form an enzyme-bound aminoacyl adenylate complex and then the complex reacts with tRNA to give aminoacyl-tRNA. It is thought that there

are at least as many individual synthetases as types of amino acid and each enzyme recognizes several isoaccepting tRNAs. While each synthetase catalyses the same general type of reaction, they vary in size and quaternary structure.

The catalytic mechanism of aminoacyl-tRNA synthetase requires at least four steps, aminoacyl adenylate formation, recognition of cognate forms of tRNA, binding of tRNA to the enzyme and transfer of amino acid to tRNA. Recent work from Schimmel's group¹ has shown that at least two of these steps are related by demonstrating that a covalent bond between uridine 8 of *Escherichia coli* tRNA^{Ala} and its respective synthetase appears to be linked with enzyme activity. They further suggest that this covalent bond may be essential for active enzyme conformation.

While tRNAs vary considerably in length and nucleotide sequence, all cytoplasmic tRNAs have uridine (or 4-thiouridine) at position 8 of the nucleotide chain. This residue lies on the

Graham Cowling is at Searle Research and Development, P O Box 53, Lane End Road, High Wycombe, Bucks

Michael addition between a synthetase nucleophile and the uracil ring

inside of the vertex made by the tertiary L-shaped structure of tRNA and is well positioned to interact with synthetase. Previous observations suggest that synthetase binds tRNA by a transient, covalent bond between a uridine residue and a nucleophilic site on the protein. Synthetases seem able to catalyse the exchange of hydrogen atoms at C-5 of uridine 8 in cognate tRNAs, a reaction which involves nucleophilic attack by the enzyme on C-6 of the uracil ring to form a Michael addition product. Reversal of the reaction results in the observed H-5 exchange (see the figure). Similar mechanisms involving the formation of 5, 6-dihydropyrimidine intermediates are common with enzymes that modify pyrimidine nucleotides. Examples include thymidylate and pseudouridylate synthetases, dUMP and dCMP hydroxymethylases and DNA methylases.

Understanding of the action of thymidylate synthetase has been much helped by the use of uridine substrates with electron withdrawing groups at C-5. The substitution increases the susceptibility of C-6 to nucleophilic attack and thus allows the isolation of stable nucleoside-enzyme intermediates. This strategy has, however, failed in the case of aminoacyl-tRNA synthetase because the enzyme catalyses the breakdown of 5-bromouridine to give pyrimidine base, ribose and free enzyme. Schimmel *et al* solved this problem by finding conditions that increase both the formation and stability of 5-bromouridine-synthetase complexes. Experimentally, this involved using a greater excess of uridine derivative and omitting sulphhydryl reducing agents in the reaction. As a result a stable 'dead-end' complex between 5-bromouridine and synthetase accumulated. Each subunit of the tetrameric enzyme was found to bind one molecule of 5-bromouridine. If the site on synthetase which interacts with either 5-bromouridine or uridine 8 in tRNA is required for activity, binding the uridine derivative should block the binding of tRNA and destroy the aminoacylation activity. This seems to be the case and suggests a single uridine binding site on the enzyme.

E. coli Ala-tRNA synthetase is composed of four identical subunits each of 875 amino acids. It had already been shown that the N-terminal half of each chain (440 amino acids) is responsible for aminoacyl adenylate synthesis but cannot catalyse the

aminoacylation of tRNA². Schimmel and co-workers further demonstrate that the uridine binding site is at the C-terminal end of synthetase and 5-bromouridine does not interfere with aminoacyl adenylate formation. Data from segment directed mutagenesis experiments (unpublished) indicate that only a relatively short stretch of 30-60 residues in the C-terminal end of synthetase is required for effective tRNA binding.

Other recent studies point to a conformational change being part of the synthetase mechanism. Ebel and co-workers³ found that yeast Phe-tRNA synthetase was able to aminoacylate adenosine mononucleotide if the enzyme was conformationally triggered by binding defective yeast tRNA^{Phe} which has been stripped of its 3'-terminal adenosine (the normal site of aminoacylation). Baltzinger and Holler⁴ also concluded after kinetic studies of the catalytic mechanism of *E. coli* Phe-tRNA synthetase that a conformational change of

the nascent enzyme-tRNA complex is the rate limiting step. Whether the covalent bond between the synthetase and uridine 8 of tRNA plays a role in catalysis is less clear.

Schimmel *et al*⁵ speculate that the formation of such a bond may allow the domain responsible for adenylate formation to interact with the bound 3'-end of the tRNA. If this mechanism is correct, it will be interesting to discover how synthetases recognize the differences between cognate and non-cognate tRNAs. Although non-cognate tRNAs have been shown to bind to synthetase, this does not result in aminoacylation. Non-cognate tRNA mixtures also fail to undergo synthetase-mediated H-5 exchange. Assuming uridine binding does not occur with non-cognate tRNA, the synthetase must use other sequence or spatial criteria as part of its tRNA recognition step. These questions, as yet, remain unanswered. The abundance and heterogeneity in size and structure of synthetases suggest that the discovery of further diverse cellular functions will ensue. Already *E. coli* Ala-tRNA synthetase has been shown to bind to *alaS* promoter sequences, acting as a gene repressor of alanine biosynthesis⁶. □

The first meteorite stream

from David W. Hughes

METEOROID streams are common enough. Comets decay and their dust slowly spreads around the orbit forming a stream of particles in space that can be detected if the Earth intersects the stream. The August Perseids, December Geminids and January Quadrantids are examples of the displays of shooting stars produced by these intersections. The dust particles responsible usually have masses below a few grammes.

In contrast, meteorites, the rock and iron bodies that fall to the earth's surface, are much more massive and have been thought to reach the earth not in streams, but at random. Now scientists are having doubts. Seismometers left on the lunar surface by the Apollo 12, 14, 15 and 16 missions can detect meteorite impacts and as many as 150 have been recorded in a single year. Far from being random it seems that the impact rate varies throughout the year and increases between April and July.

Charles A. Wood of the Johnson Space Centre, Houston, is convinced that meteorite streams can be detected on Earth

Figure 1. The number of H chondrites with cosmic ray exposure ages between 2 million and 8 million years that have been seen to fall to the Earth in a five year interval. The top data set has typical intervals 1825.5 to 1827.5, the lower data set has typical intervals 1820.0 to 1825.0. A frequency periodicity of 31.2 years can be seen with maxima in 1813, 1838, 1867, 1899 and 1929.

David W. Hughes is a Lecturer in Physics and Astronomy at The University of Sheffield, Sheffield S3 7RH.

Fig 2 The meteorite stream is shown to the left. Meteorites hit the Earth at A, during June and July at a relative velocity of about 17 km s^{-1} . Impacts occur about every 31 yrs. γ represents the first point of Aries.

In the chart above the bars represent the time of fall of the meteorites that impact at the peaks of the flux curves given in Figure 1. There is a hint that the maximum flux occurs around June and July.

rate maxima are shown in the chart in figure 2. Obviously stream and sporadic meteorites are included here but still there is a hint that the maximum flux occurs around June and July, which happily agrees with the lunar seismic data. Meteorites in the orbit shown in figure 2 hit the Earth with a geocentric velocity of about 17 km s^{-1} so a reasonable amount of the meteorite survives the retardation in the atmosphere and falls to the surface.

Two major problems still await a solution. The first is the definition of the expected 1960 peak. Only 8 out of the 26 H chondrites falling between 1955 and 1970 have had their exposure ages determined.

The second problem concerns the orbit shown in figure 2. Conventional wisdom has meteorites originating from main belt asteroids. The solar gas content of

meteorites seems to require a long residence time in the inner solar system. A parent body in the asteroid belt, where about 10 per cent of the mass can be converted into regolith in $4.5 \times 10^9 \text{ yr}$, is ideal (see Anders, E., *Icarus* 24, 363, 1975). Short period comets absorb too little of the solar gases and can thus be ruled out as parent bodies, at least for all stony meteorite classes that have gas-rich members. Unfortunately, there are dynamic problems in getting meteorites from the main asteroid belt. Also, infrared observation of asteroids reveal an embarrassing lack of unambiguous parent bodies for the ordinary chondrites. Around 80 per cent of terrestrial meteorites are in this class. The orbit shown in Figure 2 however, is most unasteroid like and is typical of short period comets. It also has an aphelion distance similar to Chronos, the anomalous object orbiting between Saturn and Uranus.

Charles A. Wood and W. W. Mendell (*The Proceedings of the XIII Lunar and Planetary Science Conference* 877, 1982) conclude that the young H chondrite orbit is unstable and is representative of an orbital stage in the evolution of a small body which is moving inwards in the solar system. They propose that the H chondrite parent body was formed in the inner solar system, was ejected by Jupiter during the accretion epoch and has recently been pulled out of the Oort cloud to be reperturbed into a 'comet like' orbit that also intersects the Earth's orbit. The collision suffered by the parent body 4.45 million years ago gave the fragments very low velocities with respect to the centre of mass. This has resulted in the small spread of meteorites around the orbit and the clear indication of a 31 year period in the influx rate. The degree of spreading is shown by the narrowness of the peaks in Figure 1. □

and has published his findings in *The Proceedings of the XIII Lunar and Planetary Science Conference* 873, 1982. Wood has selected from a specific class of meteorites, ordinary chondrites with a high iron content (H chondrites), those with exposure ages between 2 and 8 million years. Cosmic rays bombarding the meteorites in space leave tracks of radiation damaged material analogous to the tracks produced by fission. Analysis of these tracks leads to an exposure age that for H chondrites peak around 4.45 ± 0.86 million years. It is generally assumed that H chondrites were part of a larger body which fragmented at the time. The falls of H chondrite in this group (figure 1) are clearly clumped in time. Neither's test for cyclical trends and the Kolmogorov-Smirnov test both confirm that the distribution is highly non-random. Power spectrum analysis gives a frequency period of 31.2 years. Maxima occur in 1813, 1838, 1867, 1899 and 1929.

The 31 year periodicity immediately indicates that the meteorites are clumped in space, in the early stages of forming a meteorite stream. An analogy is the Leonid meteoroid stream which has a period of 33 years, the small dust particles still being close to the parent comet. A period of 31 years corresponds (due to Kepler's Law) to a semi-major axis of 9.9 AU and, as the meteorites hit the Earth, it can be assumed that the perihelion distance is about 0.9 AU. The resulting orbit is shown in Figure 2. Meteorites on this orbit will hit the Earth at a specific time each year. The time of year of the fall of the meteorites from the three

Autoimmunity and the aetiology of insulin-dependent diabetes mellitus

from C. Ronald Kahn

ALTHOUGH their cause remains unknown, evidence has accumulated over the past decade that the two common types of diabetes, insulin-dependent diabetes mellitus (IDDM, also known as type I or juvenile-onset diabetes) and non-insulin-dependent diabetes mellitus (NIDDM, also known as type II or maturity-onset diabetes) may be aetiologically distinct. The damage found in IDDM appears to result from an autoimmune process which is directed at the insulin-producing β cells of the pancreas and ultimately leads to their destruction and the development of the

syndrome. The autoimmune process is probably triggered by some environmental factors in a genetically susceptible individual — exactly what these factors are is unknown but animal studies suggest viruses or toxins are likely candidates.

The first clues that an immune mechanism was involved in diabetes came from the association between IDDM and other endocrine deficiencies that had an autoimmune basis, such as those of the adrenal or thyroid glands¹. Patients with IDDM were also seen to have a remarkable increase in the prevalence of other organ-specific autoantibodies in their sera.

Direct evidence for cell-mediated autoimmunity directed against the endocrine

C. Ronald Kahn is at the Joslin Diabetes Center, Inc., Boston, Massachusetts 02215.

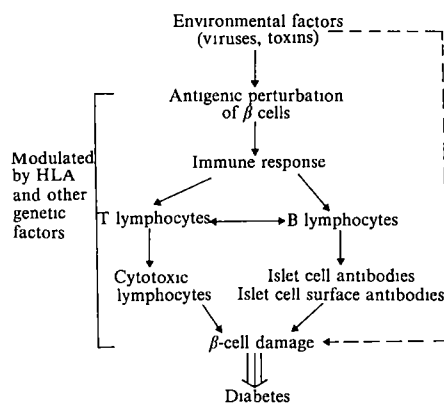

pancreas was provided in 1971 when it was found that the migration of leukocytes from patients with IDDM was inhibited by exposure to antigens prepared from endocrine pancreas². Diabetic lymphocytes also have increased adherence and cytotoxicity against cultured insulinoma cells (tumour cells of the insulin-producing β cells in the islets of Langerhans — usually benign)³. The changes in function are accompanied by alterations in the circulating lymphocyte populations in acute IDDM in both man and the BB rat, which develops an IDDM-like syndrome⁴. The passive transfer of diabetes from man to mouse and mouse to mouse using affected lymphocytes has also been reported⁵, but has been challenged as a number of groups have not been able to confirm the finding.

Despite the strong suspicion that autoantibodies might be important in IDDM, it was not until 1974 that autoantibodies against some component in the islet cell cytoplasm were detected in patients with diabetes mellitus and other autoimmune endocrinopathies⁶. Similar autoantibodies were soon confirmed in other patients and have now been found in over 2,000 diabetic patients who do not have polyendocrine failure (see review in ref 7).

As with other autoimmune features of IDDM, the exact prevalence of these autoantibodies depends on the duration of disease. Within the first one to two weeks of onset, they will be detectable in up to 85 per cent of diabetic children. This percentage rapidly declines, reaching 25 per cent by two to five years after diagnosis. The autoantibodies are present in 1–2 per cent of normal controls but their prevalence is increased in first-degree relatives of patients with IDDM and in patients with NIDDM. They are invariably of the IgG class, and, in most cases, react with the cytoplasm of all four major types of islet cells — the insulin-secreting β cells, glucagon-secreting α cells, somatostatin-secreting δ cells and pancreatic polypeptide-secreting PP cells. These autoantibodies may not be pathogenic in IDDM as only β cells are destroyed.

More recently, a complement-fixing immunofluorescence assay for detection of anti-islet cell cytoplasm autoantibodies has been used⁸. These complement-fixing antibodies seem to correlate more closely with disease. In addition, in a study currently underway, these antibodies appear to be a predictive marker of impending development of IDDM in the non-diabetic siblings of affected children.

In 1976, using a culture of insulinoma, a new class of islet cell antibodies that reacted with the surface membranes of islet cells was found⁹ and later those observations were extended using dispersed rat

Possible pathogenesis of insulin-dependent diabetes mellitus

islet cells¹⁰. Like the islet cell cytoplasm autoantibodies, the membrane autoantibodies are most prevalent in the early-onset diabetic. In the presence of complement, cell surface autoantibodies, but not cell cytoplasm autoantibodies, stimulate chromium release from radiolabelled islets and inhibit insulin release, suggesting direct cytotoxicity to islet cells¹¹. Cell surface autoantibodies, however, are also found in the sera of non-diabetic first-degree relatives of patients with IDDM.

The antigens at which the autoantibodies are directed remain to be identified. An immunoprecipitation technique¹² shows that most of the sera which contain them react with a protein of molecular weight 64,000 in ³⁵S-methionine-labelled human islet cell lysates. Hopefully, the determination of the nature of the antigen will provide a clue as to the earliest lesion in IDDM.

Circulating immune complexes have also been identified in patients with IDDM¹³. They are present not only in those patients with recent onset of disease, but also in the late phase, and in patients with NIDDM. Some of these may be immune complexes involving anti-insulin antibodies, but the widespread nature of their occurrence suggests that other antigens must be involved also.

Several animal studies suggest that virus or toxin may be the triggering factor in a genetically susceptible individual. Diabetes-like syndromes can be produced in mice by infection with encephalomyocarditis virus or reovirus^{14,15}. Reovirus also triggers production of autoantibodies that react with antigens on the surface of islet and pituitary cells, as well as antibodies that react with the hormones secreted by these cells. Likewise, insulinitis and diabetes-like syndromes can be produced by injection of low doses of β -cell toxins, such as streptozotocin¹⁴. In a series of elegant studies, Notkins and co-workers have shown that the effect of these environmental factors may be additive, and clearly varies with the genetic background of the animal¹⁵.

In humans, the precise nature of the genetic influence in the pathogenesis of

diabetes mellitus remains unclear as IDDM occurs concordantly in only about 50 per cent of identical twin pairs¹⁶. Alleles of the major histocompatibility system (the HLA system) are clearly associated with the occurrence of IDDM. Both HLA DR3 and DR4 are associated with a three- to fivefold increase in risk for IDDM¹⁷. Although there is no difference in risk between heterozygotes and homozygotes, the risk of disease to the double heterozygote — the individual with DR3/DR4 — increases almost 10-fold, suggesting that the effect of these antigens is dominant but involves independent mechanisms. HLA antigens in linkage disequilibrium with DR3 and DR4, such as B8 and B15, show similar associations. HLA B8/DR3 are associated with a persistence of islet cell surface autoantibodies in patients with IDDM^{7,8} and also appear associated with antibodies to a specific 38,000 molecular weight antigen¹². By contrast, NIDDM is not associated with any specific HLA alloantigens, but is clearly genetically influenced since it occurs in identical twins with almost total concordance¹⁶.

The recognition of the possible important role for autoimmunity in IDDM has led to attempts to suppress immune response. In mouse and rat models of IDDM, immune suppression by irradiation, neonatal thymectomy, anti-lymphocyte serum or bone marrow transplant decreases the incidence of clinical disease¹⁸. At present it is too soon to know whether these techniques will alter the course of the human disease, but they certainly present hope for the first new approach to the therapy of IDDM since the introduction of insulin over 60 years ago. □

Blue sunlight extinction and scattering by dust in the 60-km altitude atmospheric region

M. Ackerman, C. Lippens & C. Muller

Belgium Institute for Space Aeronomy, Circular Avenue 3, B-1180 Brussels, Belgium

P. Vignault

Centre d'Essais des Landes, F-40520 Biscarosse, France

Twilight data obtained photographically from a stratospheric balloon platform in the autumns of 1980 and 1981 and in the spring of 1982 are presented for blue and red light. They indicate the presence of a light absorbing layer and of a scattering layer in the mesosphere at altitudes near 60 ± 10 km with a low scattering albedo (0.1) at $0.44 \mu\text{m}$ if it is accepted that both the extinction and scattering originate from dust. The optical efficiency of the layer increases more than 10 times when the wavelength of the interacting light changes from 0.65 to $0.44 \mu\text{m}$. At the zenith and near sunset, the natural $0.44\text{-}\mu\text{m}$ extinction optical thickness and the cm^2 column scattering rate due to this layer are found to be 6.6×10^{-2} and $0.18 \text{ MR } \text{\AA}^{-1}$ respectively on 3 May 1982 above the south-west of France.

AEROSOLS have already been optically observed in the upper atmosphere from spacecrafts^{1,2} and rockets³⁻⁵. Twilight observations^{6,7} are also consistent with an upper-atmospheric particulate scattering. Other relevant experimental and theoretical work about upper atmospheric aerosols has been reviewed recently⁸ in a study of their possible continuous and sporadic extraterrestrial sources and fate. On the other hand, it has been known for more than 40 years⁹ that the atmosphere contains a source of optical extinction other than air and ozone in a supposedly transparent spectral region around $0.44 \mu\text{m}$. This extinction has been observed day and night using stars and the Sun as light sources and has caused some concern to those¹⁰⁻¹² interested in the accurate determination of the extraterrestrial solar flux who have attributed the extraextinction to aerosols. It has more recently been attributed^{13,14} entirely to NO_2 but the amount of this atmospheric constituent so deduced disagrees with observations based on the NO_2 extinction of IR radiation¹⁵⁻¹⁷ and based on the differential extinction measurement of blue light¹⁸⁻²³. Both the latter methods yield a smaller nitrogen dioxide abundance, 10–100 times less. Several authors^{20,21,23} have indicated the presence of an unattributed absorption at $0.44 \mu\text{m}$ in the upper stratosphere.

Observation method

The observation method used here has been described previously²⁴ and leads to the determination for various scattering angles, θ , of the radiance of the sunlit atmosphere in units of solar radiance as given by

$$R_\theta/R_0 = 6.79 \times 10^{-5} [Q_s n \sigma \phi_\theta / 4\pi + n_M \sigma_\theta] \quad (1)$$

where Q_s , σ , ϕ_θ and n are the aerosol scattering efficiency, the geometrical cross-section, the phase function and the number of particles on the line of sight and where n_M and σ_θ are the number of air molecules on the line of sight and the differential air scattering cross-section²⁵.

Two improvements were implemented in the gondola. A neutral density filter identical to the one used to photograph the Sun at elevation angles larger than 5° was remotely moved in front of the cameras to photograph the solar image at zenith angles from 76° to 95° allowing to perform atmospheric absorption measurements. When the Sun was at elevation angles larger than 5° , the lower neutral density screens being removed from the cameras field of view, the gondola was rotated about its

vertical axis by steps of 36° to obtain overlapping pictures of the Earth limb. The spectral bandwidths were $0.06 \mu\text{m}$ and $0.10 \mu\text{m}$ centred at $0.44 \mu\text{m}$ and $0.65 \mu\text{m}$ respectively.

The solar irradiance, I_0 , is attenuated by the atmosphere leading to the measured irradiance

$$I = I_0 e^{-\tau} \quad (2)$$

where the optical thickness

$$\tau = \sum (\sigma_g n_g) + [(Q_s + Q_a) n \sigma] \quad (3)$$

where, σ_g and n_g are the extinction cross-sections of atmospheric gases and their numbers of molecules on the optical path whereas Q_a is the absorption efficiency of the aerosol. Q_s , n and σ have been defined in equation (1). The scattering albedo of the aerosol is

$$\omega = \frac{Q_s}{Q_s + Q_a} \quad (4)$$

and the extinction efficiency of the aerosol is

$$Q_e = Q_s + Q_a \quad (5)$$

Observations

The 1981 balloon flight took place from Aire sur l'Adour in the afternoon of 19 October. During the ascent in the stratosphere and at ceiling altitude, the winds carried the balloon mainly southwards in such a way that observations took place near 43°N and $0^\circ30'\text{W}$ from 1530 to 1730 h GMT. Radar tracking was performed by the Centre d'Essais des Landes using a transponder carried with the gondola. Temperature and wind and ozone soundings were made, respectively starting at 1059 and 1336 h GMT from $44^\circ21'\text{N}$ and $1^\circ14'\text{W}$. From the beginning of the scattering measurements to the end of the absorption measurements the balloon altitude decreased from 34.3 to 33.2 km.

The observed solar irradiances, I , at $0.44 \mu\text{m}$ are plotted against solar zenith angles, χ° , in Fig. 1a as well as their theoretically evaluated evolutions from $\chi = 91^\circ$ towards smaller and larger values of χ . Rayleigh extinction by air has only been taken into account and represents fairly well the change of I from $\chi = 91^\circ$ to 94.3° . A small maximum of excess extinction is observed centred at $\chi = 92.5^\circ$. It corresponds to an optical thickness $\tau \approx 0.06$ which, if attributed to NO_2 , leads to an integrated amount on the optical path of 10^{17} molecules cm^{-2} .

Fig. 1 *a*, Solar irradiances versus solar zenith angles observed on 19 October 1981. The circles represent the measurements while the dashed curve represents the expected variation from Rayleigh extinction, the main expected component at $0.44 \mu\text{m}$. The observed solar irradiance at $\chi = 91^\circ$ has been taken as a baseline for the computation. *b*, Solar irradiance observed on 3 May 1982 from a flight level of 6.1 mbar at $0.44 \mu\text{m}$ versus solar zenith angles χ . The values represented by the solid curve have been computed taking the extinction optical thicknesses shown in Fig. 2 and the extraterrestrial solar irradiance indicated by the arrows (I_0). *c*, As *a* but for $0.65 \mu\text{m}$. The only absorber which can be considered in this case at $\chi = 90^\circ$ is O_3 leading to a radiance reduction of 12%. No excess extinction can be detected with certainty.

at 28 km grazing altitude, a small value, if compared with previous determinations.

We wish to point out the difference between the theoretically expected and the observed evolution of I in the range $90^\circ > \chi > 76^\circ$. An excess of extinction decreasing slowly with increasing solar elevation is observed. This excess has been reported previously as shown in Table 1. Its slow evolution with zenith angle indicates that its cause lies well above flight altitude. No presently known gaseous absorber can explain the observed extinction. At $0.65 \mu\text{m}$, an optical thickness change of 0.1 can be detected in the measurements from $\chi = 76^\circ$ to 90° corresponding within experimental uncertainties to the expected variation of the ozone extinction. This leads to the first conclusion that a spectrally selective extinction takes place in the upper atmosphere at $0.44 \mu\text{m}$, of which the origin is up to now unknown. Assuming that the Chapman function is valid for $\chi < 75^\circ$, the total optical thickness at $0.44 \mu\text{m}$ on 19 October 1981 at $\chi = 90^\circ$ and at 34 km altitude may approach unity.

On 3 May 1982, another evening flight took place from Aire sur l'Adour. The gondola reached a ceiling pressure level equal to 6.1 mbar with a maximum radar measured altitude of 36.6 km. The solar extinction data are shown in Fig. 1*b*. Here again an excess extinction appears at $0.44 \mu\text{m}$ for solar zenith angles $< 90^\circ$. Figure 1*c* shows the solar extinction curve at $0.65 \mu\text{m}$. Taking into account an optical thickness of 0.1 in red light due to ozone at a zenith angle of 90° , no additional or excess absorption can be measured reliably.

The solid curve fitting the data on Fig. 1*b* is the result of a computation taking into account the optical thicknesses vari-

ation versus zenith angle shown in Fig. 2 for air (Rayleigh scattering), NO_2 and X, the unknown absorber.

To evaluate the effective altitude of X, the fraction of its maximum optical thickness τ , reached at $\chi = 90^\circ$, has been computed for various values of χ . The result is shown in Fig. 3*a*. The relative value of the extraterrestrial solar radiance indicated in Fig. 1*b* has been chosen to provide the best fit to a theoretical dependence of τ versus χ leading to an effective altitude of $60 \pm 10 \text{ km}$.

The NO_2 optical thickness shown in Fig. 2 associated with a molecular extinction cross-section of $6 \times 10^{-19} \text{ cm}^2$ leads to a total stratospheric vertical content of NO_2 of $10^{16} \text{ molecules cm}^{-2}$.

The Earth limb radiances observed in the range of zenith angles, χ° , from 86° to 93° are shown in Fig. 4 for two flights: 15 October 1981 at 37 km altitude (only mainly forward scattering is shown at $0.44 \mu\text{m}$ and at $0.65 \mu\text{m}$) and 19 October 1981 at 34 km altitude (scattering angles from 14.5° to 166° at $0.44 \mu\text{m}$ and from 10.5° to 51° at $0.65 \mu\text{m}$). The accuracy of the absolute values of R_θ/R_0 are considered to be $\pm 50\%$ from one camera to the next, mostly due to the uncertainty in the evaluation of the high extinction of the neutral density screens. The accuracy of the relative values on a single camera is $\pm 5\%$. The radiance variation observed compared with χ° on 15 October 1980 and shown here for $\theta = 13^\circ$ is the best illustration.

Table 1 List of extinctions in excess of Rayleigh scattering extinction observed at or near $0.44 \mu\text{m}$ and at solar zenith angles $\chi \approx 90^\circ$ by means of instruments flown on various dates at various altitudes in the stratosphere.

Date	Flight altitude (km)	Range of χ°	Wave-length (nm)	$\Delta\tau$	Ref
9 February 1977	40	75–80*	445	0.18	20
15 October 1980	38	81–84	440	0.28	This work ²⁴
19 October 1981	34.1	76–82	440	0.19	This work
19 October 1981	34.1	82–90	440	0.22	This work
June–July 1973	16.0	$90^\circ \rightarrow$	430	0.57	13

The changes of optical thickness, $\Delta\tau$, are indicated for various ranges of zenith angles. The observations made from Concorde in June–July 1973 lead to an absolute value of τ deduced from absolute solar irradiance data measured at 16 km altitude and at $\chi = 90^\circ$ compared with extraterrestrial solar flux values.

* τ has deduced from a least square fit to the data available in this range of χ° .

Fig. 2 Optical extinction thicknesses due to air, NO_2 and to the excess absorber, X, necessary to interpret the extinction observations of Fig. 1*b*.

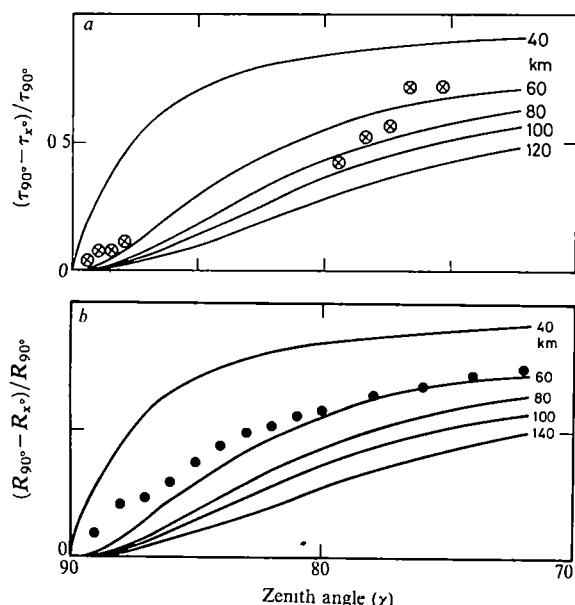

Fig. 3 *a*, Fraction of the excess extinction at $\chi = 90^\circ$ plotted against zenith angles, χ . The computed variation of this quantity versus χ for various effective altitudes (40, 60, 80, 100 and 140 km) of the X absorber. *b*, As *a*, the fraction of the excess radiance observed at $\chi = 90^\circ$ is plotted against χ . The expected variation of this quantity is also shown for various effective altitudes. It indicates an effective altitude of the excess radiance of nearly 60 km.

of the phenomenon that we wish to emphasize. Because at $0.44 \mu\text{m}$, the Rayleigh scattering should dominate the scattering, a theoretical variation of the total number of air molecules on the line of sight versus χ is fitted to the observed radiance curve at $\chi = 90^\circ$. At χ larger and smaller than 90° the observed radiance variation with χ is smaller than the theoretical one represented by the dotted curve. The cause of this difference is considered to be an excess of radiance originating from altitudes larger than the flight altitude. The dotted theoretical curve is shifted downwards to fit the observations at $\chi \approx 92.5^\circ$ where the excess of radiance becomes small compared with the air Rayleigh radiance, because lower and lower altitudes are tangentially observed at progressively larger zenith angles.

where the increasing air density must eventually dominate the scattering dependence of zenith distance. It is also observed that the excess radiance decreases slowly above the horizontal line of sight when χ° becomes $< 90^\circ$. The same phenomenon is observed on 19 October 1981 at $0.44 \mu\text{m}$ and at all scattering angles. In this case, however, the excess appears relatively smaller since the flight altitude was lower leading to a larger Rayleigh scattering due to air. A decrease of the blue and red colour ratio occurring near 1° solar depression angle, δ° , has been observed in twilight studies⁶ as well as an excess of blue light at $\delta = 0^\circ$ which was attributed to multiple scattering. In the case of our observations, however, the air observed at $\chi \leq 90^\circ$ is theoretically optically thin and multiple scattering does not explain the radiance excess, relative to pure air, linked with the anomalous radiance variation with zenith angle.

At $0.65 \mu\text{m}$, a small excess of radiance is observed at $\theta = 20^\circ$ on 15 October 1980. It is barely detectable at $\theta = 10.5^\circ$ on 19 October 1981 and it cannot be detected at larger scattering angles, being probably too small relative to Rayleigh scattering at this low flight level.

For the 3 May, 1982 flight, one of the cameras was fitted with a blue filter-equipped wide angle lens ($f = 50 \text{ mm}$) instead of the lens normally used ($f = 80 \text{ mm}$). No neutral density screen was placed in front of this camera so that the sky could be viewed over a wider range of zenith angles. The calibration of this camera was performed by comparing film optical densities of identical features simultaneously photographed by means of another blue filter, neutral density screen equipped, camera.

The limb radiances observed at two flight levels, one during the balloon ascent and the other one at ceiling altitude, are plotted in Fig. 5 against zenith angles. The variations of the number of air molecules viewed on the optical path versus zenith angles are also represented and fitted to the observations at large zenith angles ($> 90^\circ$) where pure air Rayleigh scattering must dominate.

As for the extinction in Fig. 3a, the fraction of the total excess radiance at $\chi = 90^\circ$ has been plotted against zenith angles in Fig. 3b. Here again the measurements show an effective altitude for the excess radiance near 60 km. The radiance was also observed at $0.65 \mu\text{m}$ for two flight levels as it was done in Fig. 5 for $0.44 \mu\text{m}$. The excess radiance determined in red light is 11 times smaller than in blue light. By spinning the gondola about its vertical axis by steps of 36° , the data necessary for

Fig. 4 Earth limb radiance R_θ/R_0 in units of solar radiance observed on 15 October 1980, at 37 km altitude and on 19 October 1981 at 34 km altitude versus zenith angles χ° . The observations are represented by crosses. The dashed and dotted (see text) curves represent total numbers of air molecules in arbitrary units which can be seen on the line of sight versus zenith angles χ° . The arrows marked 's' indicate the ordinate scale relevant for each graph. The scattering angles θ° , the wavelengths, $0.65 \mu\text{m}$ or $0.44 \mu\text{m}$ and the dates are also indicated. Average solar zenith angles were 78° on 19 October 1981 and 80° on 15 October 1980. For each case a vertical line indicates the $\chi = 90^\circ$ position on the abscissa where an angular difference of 1° separates two ticks, zenith angles increase towards the left-hand side of the figure.

Fig. 5 Atmospheric radiance plotted against zenith angle at $0.44 \mu\text{m}$ from two flight levels on 3 May 1982. The pure air expected radiance is represented by the dashed curves.

the determination of the phase function of the excess radiance have been obtained.

The phase functions are shown in Fig. 6 for three zenith angles in the case of the excess radiance. The values for air are those measured at $\chi = 90^\circ$. However, in the latter case the angular variation reflects the phase function at zenith angles close to 93.5° , corresponding to grazing altitudes nearing 20 km. At these low altitudes the low stratospheric aerosols and perhaps the Earth sphericity induce illumination asymmetries when the solar azimuth changes from 36° to 180° . This most probably explains the deformation of the measured air phase function shown in Fig. 6 for air. At smaller zenith angles the air Rayleigh scattering becomes quickly very small compared with the excess radiance for which it becomes only a correction factor. The phase function observed at $\chi = 80^\circ$ is for this reason used to deduce its characteristics.

The value of $Q_s n \sigma$ has been evaluated from these experimental data by means of the relationship

$$Q_s n \sigma = 1.85 \times 10^5 \sum_{0^\circ}^{180^\circ} (R_\theta / R_0) (\sin \theta \sin \Delta \theta / 2) \quad (6)$$

by zonal summation every 10° between 0° and 180° . The extinction due to scattering is found to be 2.6×10^{-2} which, according to Fig. 3b, leads, at $\chi = 90^\circ$, to $Q_s n \sigma = 6.1 \times 10^{-2}$. On the other hand, the asymmetry parameter, $\langle \cos \alpha \rangle$, is found to be 0.06.

Discussion

The extinction and the excess of radiance have been shown to originate from an altitude near 60 km, in the mesosphere. They both also exhibit a large enhancement when the wavelength changes from 0.65 to $0.44 \mu\text{m}$.

Fig. 6 Atmospheric excess radiance (a) observed at various zenith angles plotted against scattering angles θ . b, The pure air radiance phase function computed for the flight level (at 6.1 mbar) from the air differential cross-section²⁵. Solar elevation is taken as $9^\circ \pm 1.5$.

For an effective height of 60 km and an observation altitude of 35 km the optical depth factor increases 11.4 times from $\chi = 0^\circ$ to 90° . The excess extinction observed leads, according to Fig. 3, to a zenithal optical depth of 6.6×10^{-2} of which 5.4×10^{-3} is due to scattering by the dust layer. If it is accepted that the dust is responsible for both extinction and scattering in the 60-km layer, the dust scattering albedo is 0.08. This low value is compatible with very small particles exhibiting an almost symmetrical scattering phase function. One way to explain the large scattering efficiency increase when the wavelength changes from 0.65 to $0.44 \mu\text{m}$ is to consider a colour-dependent complex index of refraction in this range with a non-negligible imaginary part of the index²⁶. The dust would thus be made out of brownish matter. The complexity of the upper atmospheric dust probably having an extraterrestrial origin has already been pointed out²⁷.

Conclusion

The demonstration that a dust layer is present in the Earth's atmosphere at 60 km altitude would have a purely academic interest if it were not for its association with a non-negligible sunlight extinction and absorption *in situ* which makes it important for the Earth radiation balance, for the stratospheric and mesospheric photochemistry and energy budget and for the measurements of stratospheric trace species in blue light. These aspects justify the continued optical investigation of the layer from balloon gondola and from other platforms, and the use of other methods of investigation.

We thank the French Centre National d'Etudes Spatiales for the balloon operations and the Etablissement d'Etudes et de Recherches Météorologiques for atmospheric soundings.

Basalt genesis and mantle structure studied through Th-isotopic geochemistry

Claude J. Allègre & Michel Condomines

Laboratoire de Géochimie et Cosmochimie, Institut de Physique du Globe et Département des Sciences de la Terre, Universités de Paris 6 et 7, 4 Place Jussieu, 75230 Paris Cedex 05, France

The relative importance of the degree of partial melting and of the composition of the source, is investigated for basalts of various origins on the basis of observed Th isotopic variations. If the oceanic island basalts (OIB) and the mid-oceanic ridge basalts (MORB) are not mutually contaminated, the Th isotopic tracers show that the difference between MORB and OIB is due to a difference in the composition of their sources rather than in the degree of partial melting. The characteristics of the island arc volcanics are completely different from those for the oceanic basalts, thereby implying a difference in both their origin and their geochemical process of petrogenesis.

THE determination of the sources and the magmatic processes for basalt genesis is a key problem in petrology^{1,2}. The relative importance of these two factors in determining the different types of volcanism is also crucial. The current (popular or accepted) ideas for the three major types of volcanism can be summarized as follows. The mid-oceanic ridge basalts (MORB) would result from a large degree of partial melting whereas oceanic island basalts (OIB) mainly alkalic or of alkalic affinity correspond to a small degree of partial melting. The difference in composition of the initial material, proposed on a geochemical basis, especially from isotope studies, seems to be secondary relative to effect of the degree of partial melting, at least for the major elements. For trace elements, especially the incompatible elements, the effect of a different source or of a different degree of partial melting would be about the same.

However, the difference between MORB and island arc basalts (or andesites) would mainly result from a major difference in the composition of the sources, the MORB originating from a depleted mantle, mainly peridotitic, whereas the island arc basalts originating either by the melting of a basic downgoing slab (in the eclogite or amphibole facies) with possible mixing with sediments of continental crust, or from the melting of an hydrated peridotitic wedge.

We attempt to show here how the use of the (²³⁰Th/²³²Th) isotopic ratios measured in volcanic rocks can help in clarifying such problems and in deciphering whether the nature of the source or the processes of formation are at the origin of the differences observed among basalts. (In what follows the ratios in parentheses are activity ratios and those between square brackets are atomic ratios.)

(²³⁰Th/²³²Th)–⁸⁷Sr/⁸⁶Sr correlation in recent volcanic rocks

The measurement of (²³⁰Th/²³²Th) ratios for recent lavas from several oceanic areas has shown the existence of an anticorrelation relative to their [⁸⁷Sr/⁸⁶Sr] ratios (Fig. 1)³. The most likely interpretation for this anticorrelation is that the source regions for the basalt volcanism of these various zones are in radioactive equilibrium, and that the (²³⁰Th/²³²Th) ratios of the lavas are representative of the (²³⁸U/²³²Th)_s ratios of the mantle source, which implies a negligible time of stay at depth and of transfer of these magmas to the surface (a few thousand years at the most) relative to the ²³⁰Th half life (75,200 yr). The (²³⁰Th/²³²Th)–[⁸⁷Sr/⁸⁶Sr] anticorrelation is then indicative of a correlation between [Th/U] and [Rb/Sr] ratios of the source regions, hence of a consistency of the Th–U, Rb–Sr and Nd–Sm chemical fractionations. A low [⁸⁷Sr/⁸⁶Sr] ratio corresponds to a mantle source with time-integrated low [Rb/Sr] and [Th/U] ratios, and thus high (²³⁰Th/²³²Th) ratio. The 'bulk Earth' value of [Th/U] ratio (~3.7) can be derived from Pb isotopic studies⁴.

This value corresponds on the correlation diagram to a [⁸⁷Sr/⁸⁶Sr] value of ~0.7048, which is precisely the 'bulk Earth' Sr isotopic ratio obtained through the Sm–Nd correlation. The consistency between these different isotopic tracers is thus confirmed. We must then admit that, in the mantle, there are depleted zones for which the [Th/U] ratio is low (high (²³⁰Th/²³²Th)) and low [⁸⁷Sr/⁸⁶Sr] ratios) they are the source regions of most of the oceanic volcanism, with a minimum [Th/U] value of around 2.3. The complement of these depleted sources is probably the continental crust which should have a [Th/U] ratio higher than 3.7.

A correlation between isotopic ratios and trace elements ratios had already been suggested previously for the MORB^{5,6}. This correlation was nonlinear. When using the Th isotopes, we do not observe any curvature in the correlation which suggests that this curvature results from a chemical fractionation in the trace element ratios created by partial melting (see Fig. 1, inset).

The comparison of the actual (²³⁸U/²³²Th) ratios of the lavas and of their (²³⁰Th/²³²Th) ratios as representative of the (²³⁸U/²³²Th) ratios of the source regions, yields a simple and unique way of determining the U–Th fractionations due to the whole magmatic processes. Because the differentiation phenomena through fractional crystallization have little effect on the [Th/U] ratio, at least for oceanic volcanism, most of the Th–U fractionation can be ascribed to partial melting³. Figure 2 illustrates this process in a (²³⁰Th/²³²Th)–(²³⁸U/²³²Th) isochron diagram⁷. The point S represents the mantle source in radioactive equilibrium. Through partial melting a magma M is produced with an identical (²³⁰Th/²³²Th) ratio but a different (²³⁸U/²³²Th). The fractionation produced may be represented by a factor

$$k = (^{238}\text{U}/^{232}\text{Th})_{\text{M}} / (^{238}\text{U}/^{232}\text{Th})_{\text{S}}$$

where M and S stand for the magma and the mantle source respectively. Since

$$(^{238}\text{U}/^{232}\text{Th})_{\text{S}} = (^{230}\text{Th}/^{232}\text{Th})_{\text{S}} = (^{230}\text{Th}/^{232}\text{Th})_{\text{M}} \\ k = (^{238}\text{U}/^{230}\text{Th})_{\text{M}}$$

Obviously, if the time of stay at depth and of transfer of the magma to the surface is significant relative to the ²³⁰Th half life then the point representative of the magma shifts along a vertical line, downwards if this point is to the left of the equiline ((²³⁰Th/²³⁸U) > 1) or upwards if the point is to its right ((²³⁰Th/²³⁸U) < 1) (Fig. 2), considering that the differentiation has no effect on the (²³⁸U/²³²Th) ratio of the magma. In this case, to determine the fractionation due to partial melting we must consider the (²³⁰Th/²³²Th)₀ initial ratio of the magma at the time of its formation. If the time of stay at depth of the

Fig. 1 Correlation diagram between $(^{230}\text{Th}/^{232}\text{Th})$ and $^{87}\text{Sr}/^{86}\text{Sr}$ ratios (from ref. 3). Inset, correlation diagram between $(^{238}\text{U}/^{232}\text{Th})_M$ ratios of the magmas and $^{87}\text{Sr}/^{86}\text{Sr}$ isotopic ratios (note the curvature of this correlation).

magma is important, its representative point on the diagram is shifted away from the $(^{230}\text{Th}/^{232}\text{Th})$ – $^{87}\text{Sr}/^{86}\text{Sr}$ correlation line because of the change in the $(^{230}\text{Th}/^{232}\text{Th})$ ratio due to radioactive decay. In this hypothesis, which may be verified through the study of the $(^{230}\text{Th}/^{232}\text{Th})_0$ initial ratios evolution of the lavas throughout the history of the volcanic region, the measurement of the $^{87}\text{Sr}/^{86}\text{Sr}$ ratio yields the $(^{230}\text{Th}/^{232}\text{Th})_0$ ratio of the initial magma through the Th–Sr isotopic correlation, hence, the fractionation parameter k for partial melting.

Characteristics of partial melting

Figure 3, in which data for recent lavas from various regions that have already been studied in detail^{3,8–12} are plotted, clearly shows that most of the regions studied plot to the left of the $(^{230}\text{Th}/^{232}\text{Th})$ – $(^{238}\text{U}/^{232}\text{Th})$ diagram. This is the case for oceanic lavas such as those from the *FAMOUS* and 30°N zones on the mid-Atlantic ridge, for lavas from Afar, from oceanic islands such as Iceland, Hawaii, Faial (Azores) and La Reunion, from Etna and Stromboli¹³ and those from the continental alkali volcanism of the Chaîne des Puys (Massif Central, France).

However, some lavas plot to the right of the equiline. These all come from subduction zone volcanism such as Costa Rica⁸ and Japan (unpublished data). This type of volcanism, thus, seems quite distinct from the general case for which $(^{230}\text{Th}/^{238}\text{U})$ is >1 .

We will now consider the case of the volcanism in oceanic regions and that in subduction zones.

Oceanic basalts

The fact that all recent oceanic lavas plot to the left of the equiline has a fundamental implication about the partial melting. The latter fractionates the $[\text{Th}/\text{U}]$ ratio (whereas crystal fractionation does not) and would produce a magma with a $[\text{Th}/\text{U}]$ ratio larger than that for the mantle source. In other words, the melt is preferentially enriched in Th relative to U ($D_{\text{Th}} < D_{\text{U}}$). Indeed, these studies demonstrate that most of the oceanic lavas originate from a mantle source with $[\text{Th}/\text{U}]$ ratios lower than the primitive value of 3.7 (ref. 3), thus, from a source which has already been depleted through previous partial melting events. This is in full agreement with the conclusions from Pb isotopic studies⁴. Thus, the oceanic tholeiites with the most depleted character in Pb isotopes (as in Sr or Nd) have the highest $(^{230}\text{Th}/^{232}\text{Th})$ ratio values hence the lowest $[\text{Th}/\text{U}]$ ratios for their source regions (Fig. 3).

Such a result shows that despite their highly magmaphile character, $[\text{Th}/\text{U}]$ ratios do fractionate during partial melting and therefore, using the $[\text{Th}/\text{U}]$ ratio measured in lavas to infer $[\text{Th}/\text{U}]$ mantle geochemistry and heterogeneities, is a risky exercise. This applies to Th and U, which are among the most magmaphile elements, but also to other elements such as rare

earth elements, Ta, Hf and, of course, to Tb, Sr, Sm, Nd (see refs 14, 15). A most important factor is the degree of partial melting which can be estimated through the parameter (k) previously defined as the Th–U fractionation factor between the mantle source and the magma. The larger this fractionation, the lower the degree of partial melting considering that the partition coefficients D_{U} and D_{Th} remain almost constant. The determination of the latter would allow a calculation of the degree of partial melting. This assumption that the partition coefficients D_{U} and D_{Th} remain constant might be an oversimplification. Indeed, we do not know which minerals are involved in Th–U fractionation during partial melting. Tatsumoto⁴ assumed that, among the main minerals of peridotite, clinopyroxene is the major phase involved in this fractionation. But, he emphasized that the experimentally determined clinopyroxene–melt partition coefficients indicate a Th–U fractionation in contradiction with the Pb isotopic data (that is a melt with a Th/U ratio lower than that of the mantle). He concluded that either the experimental clinopyroxene–melt partition coefficients were not applicable to natural conditions during partial melting, or that other minerals such as phlogopite, amphibole, (apatite) were involved in the partitioning between U and Th.

Nevertheless, it is quite obvious that the percentage of melt is rather variable for tholeiites from oceanic ridges or rift zones (for example ~ 0.9 at 30°N of the mid-Atlantic ridge, $k \sim 0.8$ for the *FAMOUS* zone and Iceland at 37°N of the mid-Atlantic ridge and $k \sim 0.7$ for a lava from Afar). In an environment of spreading centre there seems to be a relationship between the degree of alkalinity and the degree of partial melting as determined through the parameter k . Indeed, the basalts from Afar are more alkaline than those from the *FAMOUS* zone, the latter being themselves more alkaline than those from 30°N.

This relationship between the degree of alkalinity and the degree of partial melting determined through the parameter k , seems still to be valid (Fig. 3) for oceanic islands and even continental volcanism (Chaîne des Puys). For example, $k \approx 0.9$ for the tholeiites from Kilauea (Hawaii), $k \approx 0.8$ for the transitional tholeiites from La Réunion, $k \approx 0.7$ for the alkali basalts from the Grande Comore island (Indian Ocean) as well as for those from the Chaîne des Puys (Massif Central, France). Note that the k coefficients (0.9–0.7) appear to be similar to those determined for the MORB, whereas the $(^{230}\text{Th}/^{232}\text{Th})$ ratios are clearly lower and more variable, indicating different, less depleted mantle sources. The difference in the degree of melting does not seem to be the primary cause of the chemical difference between MORB and OIB. The difference between the source regions and their more or less depleted character thus appear more important than the actual percentage of partial melting.

If the OIB were actually derived from a lower degree of partial melting of mantle material than MORB, then the partition coefficients D_{U} and D_{Th} must be different in these two cases and would probably be related to two mantle sources of different chemical and mineralogical composition. As a corollary to what we know about Sr and Pb isotopic ratios, the two

Fig. 2 Isochron diagram showing the geochemical behaviour of the ^{230}Th – ^{238}U system during partial melting and fractional crystallization (see refs 3, 11 for general explanation). S, magma source, M, primary magma, I_1 , I_2 , different lavas erupted at different times. White arrows represent partial melting, black arrows represent radioactive decay.

Fig. 3 Isochron diagram showing the different magmas of various sources. Data are from refs 3, 9–13, 16 and Condomines *et al* unpublished results. The lines corresponding to different fractionation coefficients k are indicated (see text). The upper horizontal axis is calibrated in $[^{232}\text{Th}/^{238}\text{U}]$ atomic ratios. The dashed arrows denote long transfer times of the magmas and the supposed positions of the primary magmas are then indicated (Etna, Chaîne des Puys, Hawaii).

domains representative of the MORB and OIB are not completely disconnected and a gradual transition does exist. Is the latter either a superficial translation of a real chemical zoning in the mantle or, conversely, an indication of mixing and contamination phenomena during the genesis and the transfer of magmas?

In the latter hypothesis, the position of the magma in the isochron diagram is no longer related to the degree of partial melting. Let us consider, for example, the following simple model⁵ an homogeneous lower mantle with a 'primitive' $[\text{Th}/\text{U}]$ ratio of 3.7 and a depleted upper mantle with a $[\text{Th}/\text{U}]$ ratio of ~ 2.3 (this is the minimum value obtained by extrapolating the oceanic trend to the equiline). The partial melting of 'blobs' from the lower mantle would yield the OIB, the partial melting in the upper mantle producing the 'normal' MORB. The mixing of these two magma types during the ascent of 'blobs' could explain the continuity of the two domains. There would be MORB more or less contaminated by the OIB magma and the reverse for OIB. In that case, the extreme values of $(^{230}\text{Th}/^{232}\text{Th})$ ratios (and Pb, Sr, Nd isotopic ratios) would be closest to the real values of these two sources. To explain the scatter of the points in the isochron diagram, each of these two mantle sources must undergo different degrees of melting (Fig. 4). It may be that the truth is in between these two extreme models (the latter simple mixing model and the model with different mantle sources for each volcanic region). The mixing model has been discussed already in the case of Iceland⁹.

It is not possible to make a definitive choice between these two models, but the ^{230}Th - ^{238}U disequilibrium data emphasize source differences among oceanic basalts. These differences might be related to chemical and mineralogical differences in the mantle composition, which would play an important part as well as the actual degree of melting, in determining the composition of the primary magmas.

Subduction zones

So far, there are only a few data available for the volcanism at subduction zones. However, a previous study of Costa Rica⁸ showed the presence of both ancient (Izaru) and recent lavas (Poas, Arenal) for which the representative points plot to the

right of the equiline in the isochron diagram (Fig. 3). This unusual behaviour is also observed for two rhyolites from the Long Valley (Sierra Nevada)¹⁶ and for lavas from the Marianas¹⁷. There are also some lavas which plot to the left of the equiline⁸ or very close to the latter (Stromboli), but it seems significant that all the lavas with $(^{230}\text{Th}/^{238}\text{U}) < 1$ come from volcanoes in subduction zone. If we admit that the partial melting fractionates the $[\text{Th}/\text{U}]$ ratio in the same manner as in oceanic basalts, then we have to find a secondary phenomenon to explain the particular position of subduction zone magmas. The arc volcanism is most probably at the origin of continental crust extraction responsible for the progressive depletion of the residual upper mantle, thus, the partial melting probably affects the $[\text{Th}/\text{U}]$ ratio in the usual way.

Another important point brought up by the magmatic evolution study of the Izaru volcano, is the variability of the $[\text{Th}/\text{U}]$ ratios of the lavas throughout the history of the volcano⁸. This is an important difference compared with the other volcanic regions studied (FAMOUS zone, Iceland, Hawaii, Etna) for which the $[\text{Th}/\text{U}]$ ratios do not vary very much. This $[\text{Th}/\text{U}]$ ratio variation for lavas from Izaru has been ascribed to a dragging of U through gas transfer during the ascent of the magma from its reservoir to the surface whereas the magma in the reservoir keeps evolving with a constant $[\text{Th}/\text{U}]$ ratio, thereby yielding an almost linear variation of the $(^{230}\text{Th}/^{232}\text{Th})_0$ initial ratios of the lavas relative to $e^{\lambda t}$ (ref. 8). If this hypothesis were correct it would demonstrate the important role of fluids in this type of volcanism and that U is far more affected than Th by the gas transfers. Would not this role of fluids, evident during the magmatic evolution, also be crucial for explaining the particular position of the magmas from subduction zones to the right of the equiline? The disequilibrium illustrated by the position of a magma to the right of the equiline may either be acquired at the time of its formation through partial melting or be the result of a source already in radioactive disequilibrium and having a similar position in the diagram.

Among the models proposed for the genesis of magmas from subduction zones, one does not seem to be compatible with the disequilibrium data: that of simple melting of the subduction oceanic crust. Indeed, oceanic crust has a quite low $[\text{Th}/\text{U}]$ ratio and hence high $(^{230}\text{Th}/^{232}\text{Th}) \geq 1.10$, after the resetting of radioactive equilibrium, inasmuch as an oceanic crust enriched in U by seawater should present even higher $(^{230}\text{Th}/^{232}\text{Th})$ ratios. Yet, most of the magmas from the subduction zones studied systematically have lower $(^{230}\text{Th}/^{232}\text{Th})$ ratios than those for oceanic tholeiites. If the oceanic crust is involved in the partial melting process there must be a mixing of the latter with another component. This other component may either be sediments dragged during the subduction, or the continental crust. Some detritic sediments (for example, clays) may have high $[\text{Th}/\text{U}]$ ratios, hence rather low $(^{230}\text{Th}/^{232}\text{Th})$ ratios when they reach radioactive equilibrium. Therefore, mixing with the oceanic crust at the time of partial melting may decrease the $(^{230}\text{Th}/^{232}\text{Th})$ ratios of the latter. Besides, the melt

Fig. 4 Isochron diagram showing the possible genesis of MORB and OIB by cross-contamination.

must be preferentially enriched in U relative to Th. The uranium from the sediments could have been brought into the magma by the fluids during partial melting. The contamination by the continental crust (higher [Th/U] ratios) of a magma originating through the melting of the oceanic crust and the participation of fluids from the continental crust is yet another hypothesis which is compatible with the disequilibrium data for explaining the enrichment of the magma in uranium.

We may propose a simple model to account for these remarks (1) A first melting stage at ridges with creation of MORB, after the spreading, the radioactive decay occurs and the oceanic crust 'falls down' onto the equiline but in a position corresponding to a much less depleted source. (2) A second stage of mixing with sediments and a partial melting in a wet medium which yield the expected result, or interaction of the magma with continental crust and selective contamination in U by continental fluids.

Another model for the genesis of the magmas in subduction zones considers a melting of the mantle 'wedge' right above the subducting plate. This part of the mantle would have been previously enriched in some elements through dehydration of the subducting oceanic crust and through transfer by fluids of the most soluble elements such as Rb or U (mantle metasomatism). This phenomenon could provide an explanation for the

presence of sources in disequilibrium to the right of the equiline. Note that if this model of metasomatism is correct, this phenomenon must have occurred a short time before or during partial melting (the metasomatic fluid could be the cause of partial melting), before the source returned to a state of radioactive equilibrium, which could be indicated by high ($^{230}\text{Th}/^{232}\text{Th}$) ratios that most of the available data do not show.

Considering the limited available ($^{230}\text{Th}/^{232}\text{Th}$) disequilibrium data for the volcanism in subduction zones a definite choice among the above models would be premature. However, fluids would really have an important role either during the partial melting process or after (uranium enrichment of the magma) or even before the melting (uranium enrichment of the source).

A more extensive study of volcanoes from subduction zones (especially from intra-oceanic arcs) would allow confirmation of the disequilibrium position of their magmas to the right of the equiline in the isochrone diagram. In such an instance, it would set an important characteristic for this type of volcanism and yield a method to study its origin.

We thank B. Dupré for an important comment, also R. K. O'Nions and A. Zindler for helpful comments. The manuscript has been prepared by Claude Mercier-Ronnat. This is IGP contribution NS/599.

A study of Si,Al ordering in thallium zeolite-A by powder neutron diffraction

A. K. Cheetham & M. M. Eddy

Chemical Crystallography Laboratory, University of Oxford, 9 Parks Road, Oxford OX1 3PD, UK

D. A. Jefferson & J. M. Thomas

Department of Physical Chemistry, University of Cambridge, Lensfield Road, Cambridge CB2 1EP, UK

The cubic structure of thallium zeolite-A has been studied by high resolution powder neutron diffraction. Refinements in which Si and Al are strictly alternating within the aluminosilicate framework (space group Fm3c) are better than those in which each Si is linked, by oxygen bridges, to three Al and one Si (space group Pn3n). This result is in accord with recent ^{29}Si (magic-angle spinning) NMR measurements on zeolite ZK-4 but at variance with previous interpretations of NMR measurements on the sodium form of zeolite-A. Our conclusions reaffirm earlier X-ray results.

THE growing importance of zeolite materials in catalytic reactions has led to a revival of interest in their microstructure and in particular the details of their Si,Al distributions. Until recently, zeolite-A was regarded as the most definitively characterized member of the zeolite family, with the very simplicity of its structure adding to the assurance that the description was correct. The basic framework consists of silicon and aluminium atoms tetrahedrally coordinated by oxygen (Fig. 1), but the exact ordering of Si and Al has remained the subject of debate. According to Loewenstein's rules¹, a tetrahedrally coordinated aluminium atom should not be linked through oxygen to another aluminium with the same coordination geometry. Although there are exceptions to the rules^{2,3}, they nevertheless provide a good basis for describing aluminosilicate frameworks.

Strict alternation of the Si and Al, in obedience of Loewenstein's rules, leads to a cubic cell, $a \sim 24.6 \text{ \AA}$, and the space group Fm3c (refs 4, 5). In detailed single crystal X-ray studies on sodium zeolite-A⁶ and three samples of dehydrated, potassium zeolite-A⁷, Pluth and Smith obtained excellent refinements in Fm3c, although a few weak reflections violating the c -glide were observed in each case, this was also noted by Thoeni in work on hydrated samples of thallium, calcium and silver zeolite-A⁸.

The apparent violations of the c -glide condition in some of the zeolite-A data suggest the possibility that the space group Fm3c may be incorrect, and recent observations using electron diffraction, neutron diffraction, and high resolution, magic-angle spinning ^{29}Si NMR give cause for further scepticism^{9–14}.

Table 1 Final atomic coordinates for Tl zeolite-A in space group Fm3c

Atom	Position	x	y	z	Occupancy	B(Å ²)
Si	96(i)	0 0	0 0906(5)	0 1826(5)	1 0	0 11(11)

**Fig 1** The cubic ($a \sim 12.3$ Å) sub-cell of zeolite-A, Si(Al) and oxygen atoms are shown as large and small spheres, respectively

The electron diffraction patterns of sodium zeolite-A contradict the space group Fm3c owing to the appearance of hhl reflections with $h + l = 2n$ (ref. 15), and neutron diffraction measurements on dehydrated samples of the same material show a pronounced rhombohedral distortion. The NMR studies reveal a single peak with a chemical shift (89.7 ± 0.5 ppm) in the range expected for Si surrounded by three aluminium atoms and one silicon^{12,13}. This 3:1 ordering scheme requires similar ordering for Al, in contradiction of Loewenstein's rule. A rhombohedral structural model that incorporates the 3:1 Si,Al ordering scheme has been advanced by Bursill *et al.*⁹

In an attempt to resolve the controversy surrounding the Si, Al ordering in zeolite-A, we have carried out a powder neutron diffraction study on one of the rhombohedrally distorted zeolite-A samples, having exchanged sodium for thallium. The greater neutron scattering length of Tl, compared with Na, affords the advantage of locating the exchangeable cations with greater precision.

Table 2 Bond lengths for Tl zeolite-A (Å)

Si-O(1)	1 608(14)	Al-O(1)	1 702(14)
Si-O(2)	1 628(14)	Al-O(2)	1 755(14)
2 × Si-O(3)	1 560(13)	2 × Al-O(3)	1 726(13)
Average Si-O	1 599	Average Al-O	1 728

Experimental work

The sample used in this work was prepared from the Na zeolite-A sample, Si/Al = 1:10, studied in ref. 11. Thallium was incorporated by ion-exchange at 85 °C using a saturated thallium(I) nitrate solution. The solution was changed after 24 h and the procedure repeated. Examination of the product in a Jeol 100CX TEMSCAN analytical electron microscope showed that the sodium had not been fully exchanged.

Neutron diffraction data were collected on the high resolution, powder diffractometer, D1A, at the high flux beam reactor in Grenoble, as described in ref. 14. The data were measured at room temperature in the 2θ range from 6° to 140°, with a mean neutron wavelength of 2.98 Å, and were collated using the program of Hewat¹⁵. Further data reduction and profile analysis were performed using the POWDER system¹⁶ on the Science Research Council's Interactive Computing Facility. The neutron scattering lengths used in the refinements were $b(\text{Al}) = 0.35$, $b(\text{Si}) = 0.42$, $b(\text{O}) = 0.58$, and $b(\text{Tl}) = 0.89$ (all $\times 10^{-14}$ m)¹⁷.

Results and discussion

The most striking aspect of the neutron powder pattern is the absence of any visual evidence for the rhombohedral distortion that was present in the anhydrous Na zeolite-A sample from which the Tl derivative was prepared. The conclusion that the sample is cubic was confirmed by the subsequent refinement that was carried out in space group Fm3c.

The Tl zeolite-A data were refined to a final R_{pr} of 11.33,

$$R_{\text{pr}} = \frac{\sum |y_i(\text{obs}) - \frac{1}{c} y_i(\text{calc})|}{\sum y_i(\text{obs})}$$

where $y_i(\text{obs})$ and $y_i(\text{calc})$ are the observed and calculated intensities, respectively, at the i th point on the profile, and c

Fig. 2 The observed (dots), calculated (solid curve) and difference profiles for Tl zeolite-A in Fm3c, reflection positions are also indicated

Fig. 3 a, The location of Ti(1), Ti(3) and Na(1) sites close to the 6-rings b, The location of Ti(2) in the 8-ring

is the scale factor. The final atomic coordinates and occupancy factors are given in Table 1, and the observed and calculated profiles are shown in Fig. 2. The lattice parameter obtained was 24.373 Å. The bond lengths given in Table 2 show that the Si–O and Al–O distances are unambiguously bimodal.

The ^{29}Si NMR spectrum of the Ti zeolite-A sample was essentially unchanged from that of the parent Na sample, confirming that the Si,Al distribution has been unaffected by the ion exchange reaction. The NMR result would seem to confirm the 3:1 ordering scheme for the aluminosilicate framework, and if this is indeed the case, then the neutron data should refine well in the cubic Pn3n model advanced by Bursill *et al.*, because this appears to be the only cubic model that is consistent with 3:1 ordering. The data were refined in this model to a final R_{pr} value of 13.99%. The R_{pr} value is thus >2% larger than the value obtained in Fm3c, even though four times as many atomic coordinates were refined in the Pn3n model.

The present neutron results point strongly towards the correctness of a 4:0 Si,Al ordering scheme. The bimodal Si–O and Al–O bond lengths are hard to rationalize with any other framework distribution, and the relatively poor refinement obtained in Pn3n would appear to be conclusive. If the Fm3c model is indeed correct for the Ti zeolite-A, then the position of the ^{29}Si NMR resonance at the chemical shift expected for 3:1 Si,Al ordering must be an anomaly that arises in zeolite-A because of the location of the Si in the double 4-rings. This conclusion has recently been corroborated by ^{29}Si NMR measurements on the zeolite ZK-4, which has the same aluminosilicate framework as zeolite-A^{18,19}. A further important feature of the present results is that the rhombohedral distortion is clearly dependent on the identity of the exchange-

able cations. If the 4:0 ordering scheme is correct, then the rhombohedral Na zeolite-A data should be refined in the appropriate space group for such ordering, $R\bar{3}c$. The factors influencing the rhombohedral distortion in zeolite-A, and the origin of the violations of the c -glide condition in the cubic form, remain to be elucidated.

The Ti zeolite-A structure contains two cations, Ti(1) and Ti(3), on the 3-fold axis above and below the centre of the 6-ring (Fig. 3a). These cations are trigonally coordinated by oxygens in the 6-ring at 2.715 Å and 2.923 Å, respectively, the sum of the ionic radii for Ti^{4+} and O^{2-} is ~ 2.85 Å (ref. 20). Ti(2) is coordinated by two oxygens in the 8-ring, O(1) and O(2), at 2.982 Å and 2.694 Å, respectively (Fig. 3b). Cation (4) is found surprisingly close to the centre of the 6-ring at a distance of 2.256 Å from O(3). It essentially lies between Ti(1) and Ti(3) (Fig. 3a), at the position corresponding to the cation site with the highest occupancy in sodium zeolite-A. This evidence, together with the short cation(4)–oxygen distances, the small value of the lattice parameter, and the electron microscopy results, clearly confirms that cation(4) is in fact sodium arising from incomplete cation exchange. When the scattering length of sodium is substituted for that of Ti at this site, the total cation occupancy for the compound increases from 0.72(3) to 0.91(3), the theoretical value is 0.95(2). In earlier studies²¹ of ion-exchange at 25 °C, 64% conversion from the sodium to the thallium form was obtained, our results correspond to 66% conversion. The zero-coordinated Ti atom reported by Firor and Seff²² is not found in the present work.

We thank the SERC for neutron facilities at ILL and a studentship for MME, Mr S. Heathman for experimental assistance, and the Exxon Research and Engineering Co. for a grant.

Specific protein–nucleic acid recognition in ribonuclease T₁–2'-guanylic acid complex: an X-ray study

Udo Heinemann

Abteilung Chemie, Max-Planck-Institut für Experimentelle Medizin, Hermann-Rein-Strasse 3, D-3400 Gottingen, FRG

Wolfram Saenger

Institut für Kristallographie, Freie Universität Berlin, Takustrasse 6, D-1000 Berlin 33, FRG

RNase T₁ is folded into an α -helix of 4.5 turns, covered by a four-strand antiparallel β -sheet. Specific recognition of 2'-guanylic acid arises from hydrogen bonding between main chain peptide groups and the O-6 and N-1-H of guanine, as well as from stacking of Tyr 45 on guanine. At the active site, Glu 58, His 92 and Arg 77 are involved in phosphodiester hydrolysis.

SPECIFIC recognition of certain nucleotides or nucleotide sequences in both RNA and DNA by proteins is of central importance in various processes in molecular biology. Understanding of the mechanism by which proteins express base specificity requires structural studies of model systems like nucleases and their complexes with nucleic acid fragments. So far, crystal structures of such systems have been published for bovine pancreatic ribonuclease A^{1–3} and ribonuclease S⁴ and for the nuclease from *Staphylococcus aureus*⁵. While the staphylococcal enzyme hydrolyses both DNA and RNA, RNase S acts only on phosphodiester bonds at the 3'-terminal side of pyrimidine nucleotides in single-stranded RNA.

An even more selective enzyme, ribonuclease T₁ (RNase T₁, EC 3.1.27.3) from the fungus *Aspergillus oryzae*, degrades single-stranded RNA to yield exclusively oligonucleotides with terminal guanosine-3'-phosphate. As with RNase A, RNase T₁-catalysed cleavage involves formation of an intermediate, 2',3'-cyclic phosphate, followed by hydrolysis. Its marked specificity towards guanosine has not only made RNase T₁ an important tool in nucleic acid chemistry but it is also used extensively as a model compound to study the recognition of nucleic acids by proteins⁶.

Chemical modifications of RNase T₁, a small acidic protein, have demonstrated the importance of an active glutamic acid residue⁷ and of two histidines^{8,9} for its enzymatic activity. Participation of histidine residues in substrate binding and their interaction with carboxylate groups of the protein were also demonstrated by NMR spectroscopy^{10,11} and kinetic studies¹². However, the exact role of these residues (Glu 58, His 40 and His 92) in catalysis and/or base recognition is unknown. There is also some evidence for the side chain of the single arginine (Arg 77) being located near the active centre¹³ (see Fig. 1). The positions N-1, N-7 and the 6-oxo group of the guanine base appear to be recognized by RNase T₁.

The crystallographic investigation of the RNase T₁–2'-guanylic acid complex described here was undertaken to provide a structural basis for understanding the enzyme's remarkable base specificity, and the molecular mechanism of RNase T₁-catalysed RNA cleavage.

Structure determination

As described previously¹⁴, RNase T₁ co-crystallized with 0.25% 2'-guanylic acid from sodium acetate buffer adjusted to pH 4.0–4.4 when dialysed against 53% 2-methyl-2,4-pentanediol. Crystals used in X-ray diffraction work were orthorhombic, P2₁2₁2₁, with cell parameters $a = 46.8$ Å, $b = 50.2$ Å and $c = 40.4$ Å. Heavy atom derivatives were prepared by soaking

protein crystals in 1–5 mM solutions of the respective reagent in the mother liquor.

Diffraction data were collected by a diffractometer in the ω -scan mode with stationary background counts on both sides of each reflection. Five individual data sets of native RNase T₁ and two sets of both Pb(II) acetate and Pt(NH₃)₄Cl₂ derivatives including Friedel pairs, were measured using one single crystal for each set. Reflection standard deviations were computed from counting statistics¹⁵ and the data sets were placed on a common scale after semi-empirical absorption correction¹⁶. Corresponding structure factor amplitudes were then averaged, weighted by the inverse square of their standard deviations.

Estimates of the heavy atom structure factor amplitudes¹⁷ were used to locate the heavy atom sites by Patterson syntheses and direct methods¹⁸. Heavy atom parameters were subjected to full matrix least-squares refinement and finally the enantiomorph was selected by calculating difference Fourier maps based on protein phases derived from either hand of the sites.

Fig. 1 Covalent structure of RNase T₁ (ref. 21). Residues shown shaded are critical for enzymatic activity. The protein used in this investigation was an isoenzyme of the sequenced species, having one additional lysine residue and lacking one glutamine or glutamate⁴⁸. Preliminary results of the amino acid analysis of iso-RNase T₁ (H. Kratzin, personal communication) suggest that Gln 25 is exchanged with Lys. The present X-ray study showed Gln 25 or Gln 85 as possible exchange positions. Enzymatic activity of the iso-RNase T₁ is the same as that of the mother protein.

Table 1 Data collection and processing statistics

Derivative	Minimum resolution (Å)	Reflections measured*	Unique reflections*	R_M	R_I	R_A	Heavy atom sites	R_{FHLE}	Phasing power
Native RNase T ₁	2.5	14,318	3,550	0.098	—	—	—	—	—
Pb(II) acetate	2.5	5,793	3,547	0.066	0.272	0.109	6	0.394	2.327
Pt(NH ₃) ₄ Cl ₂	2.5	4,897	3,139	0.051	0.159	0.125	2	0.372	2.056
Pb/Pt	3.0	1,970	1,970	—	0.149	0.108	3	0.377	2.259

Preparation of heavy atom derivatives Pb(II) acetate, crystals were soaked for 1 day in a 1 mM solution, Pt(NH₃)₄Cl₂, 2 days in a 5 mM solution, double derivative (Pb/Pt), first 1 day in 1 mM Pb(II) acetate, then 2 days in 5 mM Pt(NH₃)₄Cl₂. Individual R values are defined as

$$R_M = \frac{\sum_i |F_i - F_i^+|}{\sum_i F_i}, \quad R_I = \frac{\sum_i |F_i - F_{PH}|}{\sum_i F_i}, \quad F_A = \frac{\sum_i |F^+ - F^-|}{1/2 \sum_i (F^+ + F^-)}, \quad R_{FHLE} = \frac{\sum_i |F_{HLE} - F_{H(calc)}|}{\sum_i F_{HLE}}$$

Summations are over all reflections. F_P is the protein structure factor amplitude, F_{PH} the derivative structure factor amplitude, F^+ and F^- the positive and negative equivalents for Friedel pairs. F_{HLE} and $F_{H(calc)}$ are the estimated¹⁷ and calculated heavy atom structure factor amplitudes, respectively. The phasing power is defined as $\sum F_{H(calc)} / \sum E_{best}$, where E_{best} is the lack of closure error at the centroid protein phase.

* For derivatives, Friedel pairs were counted as one reflection.

of the platinum derivative. Conventional Blow and Crick phase determination¹⁹ yielded a mean figure of merit $\langle m \rangle = 0.75$ for all 3,547 reflections to 2.5 Å. Data processing and heavy atom refinement statistics are given in Table 1.

Map interpretation

An electron density map was calculated for protein phases obtained as described above and sampled at grid spacings of 0.9 Å. Positive density was contoured at a scale of 1 Å = 2 cm on transparent plastic sheets, which were placed in an optical comparator²⁰ for the construction of a Kendrew wire model of the RNase T₁-2'-guanylic acid complex.

From a first inspection of the map, the molecular boundaries of the ribonuclease molecule and the bound nucleotide were immediately apparent. The base, ribose and phosphate portions of 2'-GMP were well resolved. Once the chain termini were identified, tracing of the protein polypeptide chain was straightforward. In general, carbonyl 'bumps' were visible and in the pleated sheet structures, some hydrogen bonds were indicated by weak electron densities. Most amino acid side chains are clearly defined and in agreement with the published sequence²¹. The side chain of Lys 41 which points towards the solvent, however, has no density beyond its C β atom, probably a consequence of disorder. Coordinates of the 801 atoms of the complex were directly determined from the model and will be deposited with the Brookhaven Protein Data Bank.

RNase T₁ is a compact molecule

As illustrated in the schematic drawing in Fig. 2, the RNase T₁ molecule is a compact, globular protein whose shape may be defined as a slightly distorted tetrahedron with corner positions

Fig. 2 Schematic drawing of the RNase T₁ polypeptide folding. Taking into account residues which occur in reverse β -turns, half the molecule consists of well-defined secondary structure. Numbers refer to amino acids in the primary sequence (see Fig. 1).

occupied by the side chains of residues Ala 1, Glu 31, Asn 83 and Ser 96. Molecular dimensions are 32 × 33 × 30 Å measured along the unit cell axes. Individual RNase T₁ molecules in the crystal lattice are largely separated by solvent regions, with only three obvious intermolecular contacts involving one hydrogen bond between the side chains of Glu 46 and Ser 35.

The polypeptide chain connecting amino acid residues adjacent to the amino-terminus almost forms a closed loop, which is held together by the disulphide bridge between residues 2 and 10. The chain then enters a regular α -helix of ~4.5 turns, followed by two wide loops separated by a stretch of extended structure to which the inhibitor is bound. Three strands of antiparallel pleated β -sheet follow, with another loop inserted after the first strand. The structure is completed by a wide turn, bringing the carboxy-terminus into the vicinity of the amino end and closing the disulphide bridge 6-103.

While the α -helix is entirely regular, the pleated β -sheet structure is severely bowed and twisted in a left-handed sense. The hydrogen-bonding pattern between backbone segments Asp 76 to Asn 81 and Asn 84 to Ile 90 is disturbed by insertion of residues in the latter strand, residue Val 79 forming a classical ' β -bulge'²² with the dipeptide Ala 87-Gly 88. Another peculiarity of RNase T₁ concerns proline residues 39 and 55 which fit the electron density best when in *cis* form.

The globular structure of the RNase T₁ molecule hides a hydrophobic core located mainly in the interface region between the long α -helix and the pleated sheet. Therefore, all hydrophobic side chains of RNase T₁ are at least partially protected against solvent contact.

Unlike bovine pancreatic ribonuclease, RNase T₁ does not provide a distinct cleft for substrate binding. In view of the outstanding specificity of RNase T₁, it is surprising that the inhibitor base is bound merely on the enzyme surface, while the 2'-GMP phosphate portion lies in a shallow concave depression. A characteristic assembly of aromatic side chains around the active site region might be involved in sub-site interactions with adjacent nucleotides along the polynucleotide chain, this would be in agreement with kinetic studies^{23,24} which have revealed differences in the hydrolysis of GpN substrates.

Positive charges cluster in a narrow zone

It is an apparent paradox that RNase T₁ is an acidic protein exhibiting an isoelectric point of 3.8 (ref. 25), while its function is to bind to and degrade negatively charged nucleic acids. It shares this property with ribonuclease U₂ (from *Usulago sphaerogena*⁶) and ribonuclease St from *Streptomyces erythreus*²⁶, but not with the ribonucleases from *Bacillus amyloquelaceus* and *Bacillus intermedius*, which belong to the same sequence-related family of enzymes²⁷. On complex formation, some of the counter-cations of the RNA must be replaced by the ribonuclease to allow close intermolecular contacts, followed by cleavage of the phosphodiester bond. Therefore it is of interest to examine the distribution of charges on the molecular surface of RNase T₁.

Fig. 3 Stereo drawings of the RNase T₁ molecule *a*, The whole RNase T₁-2'-GMP complex with the protein backbone and the nucleotide indicated by heavier lines *b*, C^α-backbone and acidic residues *c*, C^α-backbone and basic residues The side chain of Lys 41 is not visible in the electron density map and is indicated by its C^β-atom only *d*, C^α-backbone with 2'-guanylic acid shown by heavier lines

At pH values of ~ 5 , where RNase T₁ has maximum affinity for small substrate analogues²⁸, most carboxylate groups are deprotonated, while the basic residues including the histidines bear a positive charge. The resulting charge distribution of the RNase T₁ molecule is shown in Fig 3*b,c*. Except for the side chain of Glu 58, all charged residues are located on the molecular periphery, the acidic groups being equally distributed over the whole surface. The side chains of the basic residues His 40, Arg 77 and His 92, however, are arranged in a narrow zone around the active site (see below) and form the environment for the binding of the inhibitor phosphate group. On this

basis, it is tempting to deduce a function for the charged residues of RNase T₁ in promoting the attachment of its shallow active site groove to the negatively charged nucleic acid via electrostatic interactions.

Protein-nucleic acid recognition is specific

In the complex formed between RNase T₁ and 2'-GMP, the ribose moiety of the nucleotide adopts a C-3'-*endo* type puckering, the orientation about the C-4'-C-5' bond is +*gauche* and the torsion angle defined by the glycosyl link is in the *syn* range.

Fig. 4 Base recognition by RNase T₁. 2'-GMP is shown together with the portion of the RNase T₁ polypeptide chain from His 40 to Tyr 45. Note the hydrogen bonds (broken lines) between base positions N-1 and O-6 and the protein backbone and between the His 40 imidazole and the inhibitor phosphate moiety. The wide curved arrow indicates interactions between the O-6 of guanine and the side chain of Tyr 42. The phenyl ring of Tyr 45 stacks parallel to the guanine plane, 3.5 Å distant. The electron density map shows some evidence of an alternative, non-stacking position of the side chain of Tyr 45 which would require rotation around the C^α-C^β and C^β-C^γ bonds.

The latter conformation is unusual but not unexpected. Thus, it has been proposed earlier on the basis of circular dichroism spectra²⁹ that guanosine nucleotides bind to RNase T₁ in this particular form and there is evidence for easy conversion from *anti* to *syn* conformation of guanosine, the latter even being preferred in acidic medium.^{30,31}

The guanine base of the inhibitor is bound to the polypeptide backbone of RNase T₁ by hydrogen bonds between the N-1—H of guanine and the main-chain carbonyl of Asn 44 and between O-6 of guanine and the main-chain —NH of Asn 43 as shown in Fig. 4. This result is consistent with the requirement of the guanine N-1 and O-6 positions for base recognition by RNase T₁ (ref. 6). The geometry of the guanine-RNase T₁ interactions also suggests that substitution of the guanine base at N-7 would interfere sterically with the backbone carbonyl group of Lys 41, and that protonation of N-7 by the enzyme, as suggested on the basis of proton NMR studies¹¹, is unlikely. This is because, first, we should observe strong hydrogen bonding between guanine N-7 and RNase T₁ (this is not found) and second, the *pK_a* of guanine N-7, 2.8, is too low to induce protonation in crystallization conditions at pH 4.0–4.4. A NMR investigation of the binding of ¹⁵N-enriched 3'-GMP to RNase T₁ (ref. 32) also did not support the proposed N-7 protonation; this experiment has been interpreted in terms of a strong interaction of the amino group at guanine C-2 with RNase T₁. In the X-ray structure, however, no close contact with the guanine amino group is observed, therefore it is not essential for RNase T₁-guanine recognition. This finding is in agreement with chemical studies demonstrating that substrates in which inosine is substituted for guanosine are converted at almost the same rate.⁶

In addition to these hydrogen-bonding contacts, our model indicates interactions between guanine O-6 and the phenyl moiety of Tyr 42 and, more importantly, stacking between the guanine base and the phenyl residue of Tyr 45. The latter lies 3.5 Å 'above' the base at the very periphery of the complex. As the map shows a neighbouring portion of weak electron

density probably representing an alternative location of the Tyr 45 side chain, a conformational change of RNase T₁ on substrate binding is probable, swinging Tyr 45 over and into a stacking position with the guanine base. This movement locks in guanine after it has entered the active site following recognition, by hydrogen bonding to the main-chain atoms of Asn 43 and Asn 44. In agreement with these observations, earlier studies showed that the fluorescence of one or two tyrosines is affected when RNase T₁ is complexed with substrate analogues³³, and the above-mentioned NMR results should be reinterpreted in this light.

There is no apparent interaction between RNase T₁ and the ribose of 2'-GMP but the phosphate is involved in hydrogen bonding to the imidazole of His 40. As the phosphate group is near the side chains of His 40, Glu 58, Arg 77 and His 92 which line the active site of RNase T₁ (see below), it is possible that the more natural analogue 3'-GMP would involve other interactions of its ribose and phosphate portions. Thus, slight rotation about the glycosyl link would bring the ribose O-5' hydroxyl in hydrogen-bonding contact with Asn 98, and the 3'-phosphate would be in a position to hydrogen bond with His 92 and also with Arg 77 if this side chain were rotated into another position.

In this regard, it is of interest that the *anti*-fixed nucleotide derivative 5'-deoxy-8,5'-cyclo-guanosine-2',3'-cyclophosphate is bound to RNase T₁ and is converted to the corresponding 3'-phosphate³². As the rate of hydrolysis is rather slow compared with guanosine-2',3'-cyclophosphate, we assume that the base binds nonspecifically to the enzyme (probably promoted by stacking with Tyr 45) whereas the sugar-phosphate moiety protrudes into the active site and is cleaved. This interpretation also explains why dinucleoside phosphates with other than guanosine in the 5'-position are hydrolysed by the enzyme, although at dramatically reduced rates (a factor of $\leq 10^{-6}$) (ref. 6).

Why is the protein main chain involved in specific recognition?

When considering the specific protein-nucleic acid recognition, the often discussed side chain-base interactions spring to mind.^{34,35} In the case of guanine, these could involve Asp or Glu carboxylate accepting hydrogen bonds from guanine N-1—H and N-2—H, Arg guanidinium donating hydrogen bonds to N-7 and O-6, or Gln, Asn amide groups donating and accepting hydrogen bonds to O-6 and from N-1—H, respectively. It is surprising to find that in the RNase T₁-2'-GMP

Fig. 5 Catalytic centre of RNase T₁. The plane of the guanine base is almost perpendicular to the plot.

complex none of these interactions is observed and that the nonspecific main chain peptide groups have been selected for specific recognition

Why is this so? One reason could be that amino acid side chains are floppy because of rotations about C—C single bonds, and therefore do not provide for a well-determined matrix necessary for fast, highly specific mutual recognition of the two partners. Alternatively, the main chain can be adjusted and maintained in any conceivable configuration, with peptide groups in fixed positions and ideally suited as hydrogen bonding donors and acceptors. This allows for much better fine-tuning of these interactions than utilization of amino acid side chains. Furthermore the folding of the chain can be designed to be stiff or flexible, depending on the respective needs to be served.

Catalytic site geometry suggests mechanism of RNA hydrolysis

The catalytic centre of RNase T₁ is shown in Fig 5. His 40, in the immediate neighbourhood of the side chain of Glu 58, forms a hydrogen bond or salt bridge with the 2'-GMP phosphate group. The His 92 imidazole ring points towards the phosphate portion of the inhibitor, but is too far away to interact directly with it, whereas the adjacent guanidinium group of Arg 77 is turned away from the active site. The side chain of Asn 98 is close to the 3'-hydroxyl group of the nucleotide.

Proton NMR spectroscopy has revealed unusually high *pK_a* values (7.2–7.9) for two or three histidines of RNase T₁ (refs 36–38). The interpretation that these residues interact with acidic side chains of the protein is supported by the crystal structure, which shows His 27 located close to both Glu 28 and Glu 82 and His 40 near the Glu 58 carboxyl group. Interaction of His 92 with an acidic group¹², however, would require an almost complete re-folding of the protein. The interaction of His 40 with Glu 58, as observed in the electron density map, has also been deduced from NMR studies²⁸. As the side chain of Glu 58 is close to the inhibitor phosphate moiety it is presumably protonated. This is consistent with the result of potentiometric titrations of RNase T₁, which demonstrated that the *pK* of one carboxylate group is shifted from 4.9 to 7.8 on binding of 2'-guanylic acid³⁹.

Assuming a similar binding of true substrates to RNase T₁, we propose a catalytic mechanism for the enzyme where, in the transphosphorylation step, the carboxylate group of Glu 58 acts as a base in abstracting the proton from the ribose O-2' and the imidazole of His 92 protonates the leaving O-5'. The function of His 40 is merely to activate the Glu 58 carboxylate group. Obviously, this histidine is not conserved in all members of the RNase T₁ family²⁷, because it is not essential for catalysis. This mechanism for the transphosphorylation step is consistent

with an in-line mechanism⁴⁰ for RNase T₁ action as proposed by Eckstein *et al.*⁴¹ on the basis of the methanolysis of cyclic phosphorothioates.

The situation outlined above resembles that found in bovine pancreatic RNase A, where histidine residues 12 and 119 serve as general acid and base catalysts⁴². The function of the Arg 77 of RNase T₁ could be similar to that of Lys 41 of RNase S—that is, to stabilize the pentacoordinate intermediate of transphosphorylation through electrostatic interactions⁴³.

Relationship of RNase T₁ to other nucleases

The folding of RNase T₁ bears no similarity to that of *Staphylococcus* nuclease or of RNase A from bovine pancreas. In the complex between the nonspecific staphylococcal nuclease and thymidine 3',5'-bisphosphate⁴⁴, no specific interaction between the protein and the base is observed. On the other hand, X-ray diffraction studies of several inhibitors bound to RNase S^{42, 43} have revealed that the pyrimidine base forms hydrogen bonds between its N-3 atom and O¹ of a threonine residue and between its O-2 and the backbone nitrogen of the same residue. The latter bond does not occur in all inhibitor complexes investigated⁴³. The threonine hydroxyl group serves as a hydrogen bond acceptor with uracil, where N-3 is protonated, and as a donor in the case of cytosine, thus accommodating both pyrimidine nucleotides. If mechanisms of hydrolysis of the three enzymes are compared, we find that those of RNase A and of RNase T₁ are similar to one another but different from that of staphylococcal nuclease.

Recently, the chain foldings of the ribonucleases from *S. erythraeus*²⁶ and *B. amyloliquefaciens*⁴⁵ have been elucidated by X-ray crystallography. They largely resemble that found for RNase T₁, with a long helix covered by a four-strand antiparallel pleated β -sheet. These enzymes also display sequence homologies with RNase T₁, especially around the active site residues Glu 58, Arg 77 and His 92 (ref 27) of RNase T₁, which are found in a comparable arrangement in all three proteins. The importance of the active glutamic acid for the action of the *Streptomyces* enzyme has been demonstrated⁴⁶. We conclude, therefore, that the above enzymes share a common mechanism of nucleic acid hydrolysis.

To obtain a more precise description of the processes involved in RNase T₁ action, we have commenced refinement of the present model and data collection for higher resolution. The structures of the free enzyme and of complexes with guanosine 3',5'-bisphosphate and 2'-deoxy-2'-fluoroguanlyl-(3'-5')-uridine⁴⁷ will be investigated in parallel.

All computations were carried out on the UNIVAC 1100/82 of the Gesellschaft für Wissenschaftliche Datenverarbeitung, Göttingen. We thank Professor Ruterjans and co-workers for supplying purified RNase T₁.

Sequence specificity of trinucleoside diphosphate binding to polymerized tobacco mosaic virus protein

John J. Steckert & Todd M. Schuster

Biochemistry and Biophysics Section, Biological Sciences Group, University of Connecticut, Storrs, Connecticut 06268, USA

The binding of trinucleoside diphosphates to long helical rods of tobacco mosaic virus (TMV) protein is shown to depend on base sequence, 5' AAG 3' binding being the strongest of the 25 trinucleoside diphosphate sequences measured. As TMV has a stoichiometry of three nucleotides per protein subunit, the sequence of TMV RNA suggested to be the nucleation site for self-assembly of the virus has three possible binding frames. From our binding constant data the most likely frame is predicted and shown to have two contiguous AAG sequences in a hairpin loop region.

THE mechanism of spontaneous self-assembly of tobacco mosaic virus (TMV) from its component RNA and single coat protein (TMVP) has been the subject of increasingly detailed studies. New information about the role of various TMVP aggregation states in determining the dynamics of the self-assembly process and about the molecular structure of TMVP, the whole virus and the RNA have made it possible to enquire into the chemical and structural basis for the initial recognition events between the protein and RNA.

It has been shown that TMV self-assembly proceeds by three overall processes. There is a nucleation process which involves initial binding of the protein on the RNA at a site that is $\sim 1,000$ nucleotides from the 3' end¹. Subsequent growth of the nucleoprotein complex is bidirectional and occurs by an elongation reaction involving the addition of protein to the RNA as the helical rod grows in the 5' direction, and a second elongation reaction resulting from protein addition in the 3' direction^{2,3}.

Reconstitution experiments using intact RNA and limiting amounts of TMVP, predominantly in the form of 20S two-turn (disk \rightleftharpoons helix) protein, have demonstrated the formation of short, partially assembled rods containing RNA that is nuclease-resistant and derived from the internal assembly nucleation site⁴. The nucleotide sequence of the protected portion of the RNA has been determined⁵ and overlaps much of the sequence determined in an independent effort which used a different protection strategy, that is, binding of aggregates of TMVP to

fragments of TMV RNA generated by limited ribonuclease digestion⁶. These two studies have led to two different proposals of a stable hairpin-loop secondary structure for the RNA at the nucleation site. The hairpin-loop structure is proposed to be important for the nucleation of TMV assembly because it could allow the RNA to bind from within the hole of the initiating two-turn (disk \rightleftharpoons helix) protein structure⁷. In addition, studies of the nucleotide sequences, under the constraint that the stoichiometry of the TMV particle (three nucleotides of the RNA molecule per 17,530-molecular weight (MW) protein subunit) be preserved, have led to the proposal that trinucleotide sequences at the assembly nucleation site form a reading frame for the initial binding of the 20S aggregate of TMVP^{5,6}.

We report here the results of equilibrium dialysis binding experiments utilizing various ³H-labelled trinucleoside diphosphates (trimers) and helical rods of TMVP formed in weak acid conditions. These experiments were undertaken to determine whether there are trinucleotide sequences that interact preferentially with TMV protein, and, if so, to quantitate the free energy contribution of trimer binding to helical rods of TMV protein to the total free energy of nucleation of TMV self-assembly. The binding measurements reveal a strong sequence specificity with respect to the strength of trimer binding, with AAG being the strongest ($12 \times 10^3 \text{ M}^{-1}$). These results suggest that the initial protein-nucleic acid recognition probably occurs in a hairpin-loop region of the RNA and has the binding frame —CAG/AAG/AAG—. This frame of the sequence can provide ~ 16 kcal of binding energy per mole of sites for the nucleation reaction in TMV self-assembly.

Dependence of binding on trimer sequence

Our initial attempts to measure trinucleotide binding to TMV protein, carried out in collaboration with Professor O. C. Uhlenbeck (University of Illinois), were performed at pH 7.0. At this pH the protein exists at 0 °C as a 4S species (approximately a trimer of the 17,530-MW protein subunit) or at 20 °C as an equilibrium mixture of 4S and 20S sedimenting boundaries. The latter boundary represents a mixture consisting of two-turn disks of 34 monomers⁸ and short helices, probably about two turns long⁹. In these conditions no trimer binding was detected at the lower temperature. At 20–25 °C, however, very weak binding was detected by Professor Uhlenbeck for AAG, CAG and UAG (all nucleotide sequences given here are written 5' \rightarrow 3'). Subsequent initial binding experiments at pH 6.5, 20 °C, in which the protein existed as short helical rods¹⁰, revealed that the trinucleoside diphosphates AAG, CAG, UAG and GAA bind weakly with apparent binding constants in the range $200\text{--}300 \text{ M}^{-1}$ (J. J. S. and T. M. S., unpublished results).

The pH dependence of the binding between pH 6.0 and 7.0 may result from protonation of the carboxyl groups shown in

Fig. 1 Influence of single base substitutions in the trimer XAG on the apparent free energy of binding, ΔG^*

	$\Delta(\Delta G^*)$ (kcal mol ⁻¹)
GAG-UAG	-0.46 \pm 0.1
AAG-CAG	-0.42 \pm 0.1
AAG-GAG	-0.64 \pm 0.1
CAG-UAG	-0.68 \pm 0.1

For the base in the 5' position the binding energy is more sensitive to the NH₂ and the =O ring substitutions than it is to the size of the heterocyclic ring.

Temperature, $20 \pm 0.1^\circ\text{C}$. Binding site concentration = $5.6 \pm 0.3 \times 10^{-4}\text{ M}$ (the error denotes the range of concentrations over which different experiments were performed and not the error in any single measurement of the protein concentration). pH values are 5.40 ± 0.05 except where indicated. In most cases the binding constants are the average of those determined in one experiment from two or more samples taken at dialysis equilibrium. The errors reported (in parentheses) represent the range of binding constants determined in this way. The K values for AGA and GAG represent averages of several equilibrium measurements in two completely separate experiments, the errors indicate the range of values over the two experiments. Equilibrium dialysis experiments were performed in two ways, binding of trimers to TMV protein rods formed during (method I) or before (method II) dialysis. Method I: a solution of TMV protein as 4S protein in a buffer of KH_2PO_4 (0.033 M), K_2HPO_4 (0.017 M), and KCl (0.12 M), pH 6.47 (24°C), was slowly warmed from 0°C to 20°C resulting in the formation of short helical rods as described by Shire *et al.*³¹ When examined in the analytical ultracentrifuge at 22°C , three boundaries were observed with sedimentation coefficients, $s_{20,w}$, and weight fractions, respectively, of 33–35S, 0.17–0.20, 23–24S, 0.72–0.74, and A-protein 4S, 0.06–0.09. A 50- μl sample of the protein was equilibrated with ~ 0.3 – $0.5\ \mu\text{Ci}$ of trimer (final total concentration at dialysis equilibrium between 0.1 and $1\ \mu\text{M}$) for 12–18 h at room temperature (23° – 25°C), then loaded into a dialysis chamber. In the opposite chamber was placed 50 μl of a pH 4.97 (23°C) buffer consisting of acetic acid (0.029 M), sodium acetate (0.071 M), KH_2PO_4 (0.050 M) and KCl (0.16 M). Method II: preformed TMV protein rods were formed as in method I but the trimer was not included with the protein. After 24 h of dialysis at 20°C , the dialysates were withdrawn from the buffer chambers and added individually to lyophilized trimers. The trimer-dialysate solutions were then loaded back individually into the empty dialysis chambers to allow the trimers to dialyse into the chambers containing the preformed protein rods. In most cases the first samples were withdrawn 4–5 days after the start of the experiment. In both methods I and II, pH values of solutions removed from the chambers at the end of an experiment were determined with a pH microelectrode. Details of the dialysis chambers used here and the method of equilibrium microdialysis are described elsewhere.³² The total molar site concentration of TMV protein was taken to be the same as the total subunit concentration at the start of dialysis. It was determined spectrophotometrically using an extinction coefficient of $1.30\ (\text{mg ml}^{-1})^{-1}\ \text{cm}^{-1}$ (ref. 33) and a molecular weight of 17,530 per subunit.³⁴ ^3H -labelled trimers of specific activity between 6 and 16 Ci mmol⁻¹ were synthesized according to the method of Thach and Doty.³⁵ Precautions were taken to prevent ribonuclease degradation of the trimers³⁶ and all samples were checked for purity by paper chromatography³⁵ after synthesis, and for degradation after equilibrium dialysis. TMV protein prepared as described by Shire *et al.*³⁷ was found by Professor Uhlenbeck to be ribonuclease-free. Because the ratio of molar concentration of sites to the molar concentration of bound plus unbound trimer at dialysis equilibrium was ≥ 500 , the binding constants were calculated from the relation, $K = (R-1)/C_0$, which assumes binding to one class of independent sites. C_0 , total molar site concentration, R , ratio of c.p.m. in 3 μl withdrawn from the chamber containing the protein to c.p.m. in 3 μl withdrawn from the opposite (dialysate) chamber. Binding constants <200 – $300\ \text{M}^{-1}$ are not measurable within experimental error by this method.

the X-ray diffraction structure of TMV to be near the nucleotide binding sites.¹¹ To enhance trinucleoside diphosphate binding we used a lower pH (5–6) to reduce the net negative charge on the protein through binding of the polymerization-linked protons.¹² The titration curve of TMV protein near 20°C shows

that one proton is bound when the pH is reduced from 8.0 to 6.5 and another on reduction of the pH from 6.5 to 5.5 (refs 13–17). As trinucleoside diphosphates are negatively charged in this pH range, a significant pH-dependence of binding was expected for weak binding.

In addition to reducing the net negative charge on the protein, the binding of the two polymerization-linked protons switches the subunit conformation in the 20S disk aggregate¹⁸ to one that is very similar to that in the helical subunit array found in the whole virus.^{19,20} On binding these polymerization-linked protons, TMVP subunits polymerize to form virus-like long helical rods.^{21,22} The greater affinity of the trimers for polymerized TMV protein at pH < 6 relative to the weak binding of some of them to the protein aggregates at pH 6.5 and 7.0 (see Table 1) is considered to result from the presence of an ordered structure that exists at pH < 6 in the polypeptide chain at low radius between the centre of the rod and the region where the RNA binds to each subunit. This ordered structure has also been found by X-ray diffraction to exist in TMV¹¹ and in helical rods of polymerized TMVP formed at pH 5.5 (refs 19,20). However, the crystal structure of the 20S disk aggregate¹⁸ reveals disorder of the polypeptide chain at low disk radius.

As TMV protein subunits polymerize extensively into helical rods at 20°C and pH < 6 (the conditions in which the present systematic binding measurements were made), we used intact virus to test for nonspecific binding. Neither of two trimers that bind to the protein, AAG or CAG, show binding to intact TMV in the same conditions. Binding of the trimers to the natural nucleotide sites on the native virus is precluded by the presence of the RNA, therefore the lack of binding of AAG and CAG to TMV means that there are no trivial trinucleotide binding sites on the coat protein of the virus. The similarity of the protein subunit packing in the virus and the helical protein rods^{19,20,23} leads us to assume that RNA-free TMV protein rods also do not have trivial trinucleotide binding sites.

Table 1 gives the apparent association equilibrium constants (K) for the binding of 25 trimers to TMV protein rods. In all cases the binding (or lack of it) was the same to preformed protein rods (method II) as to rods formed in the presence of trimers (method I), thus we can conclude that no nonspecific entrapment of trimers occurs during protein polymerization in method I. In general, the binding constants were found to be independent of the way in which the experiment was performed, indicating that the binding sites are structurally alike in both types of TMV protein rod preparation. At the concentrations of trimers used, less than 0.2% of the total trinucleotide sites on the protein rods were occupied and no site interactions were detectable.

The shape of the titration curve of TMV protein at 20°C suggests that the net charge per subunit between pH 5 and 6 depends strongly on the pH (refs 13–17). As the trinucleoside diphosphates are negatively charged in this pH range we would expect, and indeed we have observed, that the measured binding constants increase with decreasing pH. The binding constant for AGA at pH 5.25 is $1.6 \times 10^3\ \text{M}^{-1}$ (by method I, not shown), which is stronger binding than that observed at pH 5.4 ($1 \times 10^3\ \text{M}^{-1}$, see Table 1).

The results in Table 1 reveal three ranges of binding constants for the trimers studied, 0.5 – 2×10^3 , 4 – 6×10^3 and one sequence, AAG, which gives a value of $12 \times 10^3\ \text{M}^{-1}$.

Although not all possible trimer sequences have been studied, the results in Table 1 provide insights into the sequence specificity of TMV protein-RNA interactions. Various comparisons are drawn in Table 2, based on the assumption that the binding constants reported are obtained at binding equilibrium, for which there is evidence (see Table 1 legend). A further assumption underlying these comparisons is that all the trimers bind in the same frame on the protein. Although the present experiments yield thermodynamic and not structural information, the reasoning presented below argues against single base recognition as a major determinant of trimer binding, therefore at least compositional isomers such as

Fig. 2 *a*, Sequence of TMV RNA around the assembly nucleation region, as determined by Zimmern⁵. Secondary structure is that proposed by Zimmern. *b*, Alignment of the sequence of trinucleotides at the assembly nucleation site of TMV RNA into a binding frame for TMV protein recognition, as suggested by Zimmern⁵. Binding constants ($10^{-3} \times K (M^{-1})$) beneath the underlined trimers are for the corresponding trimers from Table 1. *c*, Trinucleotide binding frame resulting from shifting the frame in *b* one position in the 3' direction. *d*, Trinucleotide binding frame resulting from shifting the frame in *b* one position in the 5' direction.

XXY and YXX would not be expected to bind in different frames

The comparisons in Table 2 suggest the following general rules for binding. Trimer binding is highly sequence-dependent, in support of Caspar's prediction¹². Guanosine is present in every trimer that binds and appears to lead to the strongest binding when it is in the 3' position. However, an internal pyrimidine inhibits the 3' guanosine contribution to binding, with C having a stronger destabilizing effect than U. The low percentage of C at the assembly nucleation site, relative to its percentage in the whole TMV RNA molecule, has previously been interpreted to mean that C in a trinucleotide sequence exerts a destabilizing effect on binding to TMV protein^{6,24}. The pattern of binding constants in Table 1 does not reveal a simple additive contribution of single bases to the overall free energy of trimer binding, suggesting a cooperative binding mechanism. This can be seen by considering the following comparison in which the alignment of three trimers assumes that single base contributions dominate trimer binding

Protein site			Binding constant		
1	2	3	1	2	3
A	A	G			
	A	G	A		
		G	A	A	

($10^{-3} \times K (M^{-1})$)

12 0

1 0

4 7

It can be seen that each of the protein sites can be occupied identically (neglecting end effects) in the case of the three trimers examined. If single base recognition and binding determine the strength of trimer binding largely in a simple additive manner, the observed binding constants should be almost identical, clearly, this is not the case. Similar comparisons using other examples from the data in Table 1 support the conclusion that single base recognition alone does not account for the trimer binding results. This conclusion is strengthened further if the result that the trimer AAA shows no detectable binding is included in the above comparison.

The correlations described above can be summarized in the following set of rules which accurately describe the binding or non-binding of the 25 trimers tested, and predict the behaviour of the remaining 39.

Three classes of binding trimers (5' → 3') have been found: X-Y-guanosine, X-guanosine-purine, and guanosine-X-purine. Thus, the presence of a guanosine in a trimer is necessary but not sufficient for binding as trimers containing a pyrimidine in the 3' position do not bind even if there is a guanosine in either the 5' or internal position.

A comparison of the free energies of binding for the four XAG trimers, on the assumption that they bind to the protein in the same frame, leads us to conclude that for the base in the 5' position the trimer binding energy may be more sensitive to

GAG (4 0) > GAC(0) < GAA(4 7)					

The data from Table 1 are grouped to test for the dependence of the apparent binding constants ($10^{-3} \times K(M^{-1})$) on trimer composition and sequence. The following conclusions can be drawn from these comparisons: *a*, The binding constant of a trimer depends not on nucleoside composition but on sequence (see first three entries in *b*). *b*, The presence of only purines in a trimer does not necessarily result in binding, which is seen to be strongly sequence-dependent even in a tri-purine trimer. *c*, For the trimer XAG the 5' base influences binding in the order A > C > G > U. *d*, In contrast to XAG, the binding of the trimer XGA is much less sensitive to the base in the 5' position. *e*, For the trimer AXG the internal base influences binding in the order A > U > C. *f*, All seven trimers studied which have a G in the 3' position bind. However, a G in the 5' position results in binding only if a purine is in the 3' position. All the 11 trimers which bind have a purine in the 3' position. *g*, None of the 10 trimers studied which have a pyrimidine in the 3' position bind. Ten of the possible corresponding 18 independent 3' purine-substituted trimers were measured and of these, eight exhibited binding, in contrast to the absence of binding in the parent 3' pyrimidine trimers. *h*, In most cases, a 5' purine is necessary for strong binding and substitution for a 5' pyrimidine reduces strong but not weak binding.

the NH₂ and the =O ring substituents than it is to the size of the heterocyclic ring (see Fig. 1).

As the difference in binding energies for 5' pyrimidines, $\Delta(\Delta G^*)_{py} = \Delta G^*(CAG) - \Delta G^*(UAG)$ (where R₁ is =O, see Fig. 1), is about the same as that for 5' purines, $\Delta(\Delta G^*)_{pu} = \Delta G^*(AAG) - \Delta G^*(GAG)$ (where R₁ is NH₂ or H), we assume that these substituents in the R₁ position do not influence binding and the $\Delta(\Delta G^*)$ value of $\sim 0.65 \text{ kcal mol}^{-1}$ in both reflects the NH₂ to =O substitution. Continuing on the assumption that binding is insensitive to the R₁ substituent allows a comparison of $\Delta G^*(AAG) - \Delta G^*(CAG)$ and of $\Delta G^*(GAG) - \Delta G^*(UAG)$ where the R₂ positions are the same (NH₂ and =O, respectively). This comparison yields the same value of $\Delta(\Delta G^*)$, that is, $\sim -0.45 \text{ kcal mol}^{-1}$, in both cases and suggests that this difference results from the difference in heterocyclic ring size.

These binding properties at the site for the 5' nucleoside contrast strongly with those at the 3' site. From the results for the trimer GAX (see Table 2*f, g*) it can be seen that the 3' site is more sensitive to heterocyclic ring size than is the 5' site. A detailed stereochemical interpretation of these conclusions must await elucidation by X-ray diffraction of high resolution structures of the oligonucleotide-TMV protein complex²⁵⁻²⁷ and of TMV^{11,28}.

Probable binding frame for nucleation of TMV self-assembly

Figure 2*a* shows the RNA fragment, sequenced by Zimmern⁵, which is proposed to contain the region for nucleation of *in vitro* virus assembly. The hairpin secondary structure is that proposed by Zimmern based on maximum base pairing. The non-bonded loop of the hairpin structure on the right-hand side (marked *) has been proposed to be the first part of the RNA molecule that binds to the inside of the nucleating disk^{5,7}. The three possible linear binding frames for the interaction of three nucleotides with each of the identical coat protein subunits in either the disk or helix conformation are shown in Fig. 2*b-d*.

Shown beneath each binding frame are the available binding constants for the corresponding trimers from Table 1. The frame suggested by Zimmern⁵ is shown in Fig. 2*b*. Figure 2*c* gives the trimer binding frame shifted one position in the 3' direction from Fig. 2*b*. The 5'-shifted reading frame is shown in Fig. 2*d*. A comparison of the available trimer binding constants in Table 1 with the three binding frames reveals that the trimer alignment centred around AAG (Fig. 2*d*) results in the greatest number of tight sites for protein binding.

Binding frame *d* contains the greatest number of strong binding sites and the largest total number of binding sites. Comparison of the number of trimer binding sites in the three binding frames shows that frames *b, c* and *d* have, respectively, 4, 11 and 10 binding sites with trimer affinity constants equal to or greater than $4 \times 10^3 \text{ M}^{-1}$. A more significant comparison which distinguishes between binding frames *c* and *d* is the presence of three $12 \times 10^3 \text{ M}^{-1}$ trimers in the latter and two in the former. In binding frame *d* two of the highest affinity trimers, AAG, are contiguous whereas in *c* the two AAG sequences are widely separated. To a first approximation it would be expected that trimers in such pairs contribute to binding as the product of the individual trimer binding constants. This would mean that only binding frame *d* contains a region having an affinity $\geq 10^8 \text{ M}^{-1}$. The sequence forming this region, —AAG—AAG—, is in the large loop region (marked * in Fig. 2*a*) thought to be involved in the initial binding by the disk protein aggregate^{5,7}. This loop is flanked by other trimer sequences, CAG and UUG, which bind and would thus further enhance the stability of the initial complex by $\sim 5 \text{ kcal}$ beyond the $\sim 11 \text{ kcal}$ provided by the —AAG—AAG— sequence. In general, summation of trimer binding free energies, in order to estimate free energies for larger oligonucleotides, implicitly assumes that the trimers all bind to the helical protein rods in the same binding frame. However, such an assumption is obviously not required for deriving the $\sim 11 \text{ kcal}$ provided by the hexamer —AAG—AAG— but is necessary when adding the binding energies of the adjacent trimer sequences, CAG and UUG, in the RNA loop region marked (*) in

Fig 2a Binding energies of at least ~15 kcal are probably necessary for highly specific protein-nucleic acid interactions. Co-operative binding effects between adjacent trimer sites would contribute further to the binding energy for nucleation. To estimate the minimum energy of the RNA-protein interactions, we assumed that the helical rods of TMV protein at $pH < 6$ are, to a first approximation, good representatives of TMV without the RNA^{15,19,20}. There are, however, differences in protein structure between the helical protein rods and TMV^{19,20}. Studies of the energetics of changing the protein structure in the RNA-free helical rods to that occurring in TMV in conditions of *in vitro* TMV assembly are required to define fully the energy of interaction between a trinucleotide and the RNA binding site in the final virus structure. However, the energy of this conformational change is expected to be small because the titration curves of the whole virus and the RNA-free helical protein rods are almost identical, differing by at most 0.5 kcal per mole of subunits¹⁵. Evaluation of the total free energy of assembly nucleation at $pH 7.0$ will require knowledge of the energetics of the switching of the protein conformation (disk \rightleftharpoons helix). Although there are no accurate values for the free energy of the reaction (disk \rightleftharpoons helix), one can estimate a value between 2 and 4 kcal per mole of subunits from an analysis of titration¹²⁻¹⁷ and sedimentation data⁹. The upper range of this estimate is consistent with the observed very weak binding of the AAG trimer to 20S protein which is thought to be mainly the disk aggregate at $pH 7$.

The alternative hairpin-loop structure of the nucleation region of TMV RNA proposed by Jonard *et al.*⁶ is not expected to alter the conclusion regarding the RNA binding frame for protein binding. An inspection of their structure shows that the -AAG-AAG- hexanucleotide is located at the top of the loop, and therefore is in a position on the RNA to interact with the initiating 20S protein aggregate in much the same way as is the same hexanucleotide of Fig 2d.

Discussion

These binding experiments were done in conditions that ensured a very low fractional site occupancy to avoid the complication of trimer binding to possible overlapping sites in the helical protein rods. We assume that the trimers bind to the tightest sites available to them and that they bind in an orientation similar to that of the natural RNA in the virus. There is no way of knowing from these studies alone whether the trimers were bound directly to the trinucleotide binding site of the individual protein subunits or in a site formed by two laterally adjacent subunits in the helical rods. However, based on a recent refinement of the 4 Å fibre diffraction pattern of TMV and the suggested structure of the RNA in the virus²⁸, we consider that inter-subunit trinucleotide binding would not be favoured in the conditions of our experiments. The sequence dependence of the binding affinity of trinucleoside diphosphates to TMV protein suggests that the RNA binding frame of

Fig 2d is probably the one that promotes binding to the initiating TMV protein aggregate.

The results of the binding studies described here may provide only part of the explanation for nucleation of TMV self-assembly occurring at the region of the TMV RNA molecule shown in Fig 2d, as previous studies have shown that small fragments of TMV RNA derived from parts of the molecule other than the assembly nucleation region bind to disk-like aggregates of TMV protein^{24,29}. These results have been interpreted to mean that the specificity of nucleation is defined by an RNA sequence that, once bound, promotes the quaternary conformational change of the initiating two-turn cylindrical disk to a two-turn helix⁷. However, the results reported here are consistent with the trimers binding selectively to subunits in a helical array in the (disk \rightleftharpoons helix) equilibrium.

Binding of fragments of TMV RNA can be termed non-specific if there is no concomitant switching of the protein conformation. It remains to be demonstrated whether the binding of the RNA fragments derived from the coat protein cistron of TMV RNA²⁴ (the cistron starts ~150 nucleotides from the 3' end of the assembly nucleation region³⁰) to aggregates of TMV protein results in the formation of nucleoprotein complexes having a helical structure⁶. In the three binding frames of the largest RNA fragment, T1, there are no regions of sequential binding trimers, based on the information in Table 1, that contain contiguous high-affinity AAG trimers. Tyulkina *et al.*²⁹ have shown that some of the 30S complexes formed by combining 3S fragments of TMV RNA with a preparation of TMVP containing 20S aggregates have a helical structure similar to that of TMV. Their results²⁹ and the demonstration that the T1 and P1 RNA fragments (the P1 fragment contains the assembly nucleation site sequence⁶) bind with comparable rates to the disk aggregate⁶ suggest that the secondary and tertiary structures in the TMV RNA molecule might contribute to the efficiency of the sequence specificity reported here. Certainly, the existence of higher orders of RNA structure does not sufficiently explain the sequence specificity of trinucleoside diphosphate binding to TMV protein. However, RNA folding may control the accessibility of different regions of the RNA molecule to the 20S and 4S aggregates of TMV protein. For example, it is important to know whether nonspecific binding of TMV protein to the RNA molecule is minimized by placing favourably recognized oligonucleotide sequences in the hydrogen-bonded stem regions of hairpin structures rather than in their single-stranded loops. We are confident that the sequence specificity seen for trimer binding to TMV protein is related to the specificity of nucleation as a sufficiently high concentration of AAG causes crystals of the cylindrical disk protein aggregate to dissolve²⁵. This finding suggests that the AAG trimer binds like natural TMV RNA and promotes the disk-to-helix quaternary conformational change²⁶.

We thank Dr David A. Yphantis for suggestions and discussions. This work was supported by NIH grant AI 11573.

Galaxy formation by dissipationless particles heavier than neutrinos

George R. Blumenthal*, Heinz Pagels†

† The Rockefeller University, New York, New York 10021, USA

In a baryon dominated universe, there is no scale length corresponding to the masses of galaxies. If neutrinos with mass < 50 eV dominate the present mass density of the universe, then their Jeans mass $M_{J\nu} \sim 10^{16} M_\odot$, which resembles super-cluster rather than galactic masses. Neutral particles that interact much more weakly than neutrinos would decouple much earlier, have a smaller number density today, and consequently could have a mass > 50 eV without exceeding the observational mass density limit. A candidate particle is the gravitino, the spin 3/2 supersymmetric partner of the graviton, which has been shown¹ to have a mass ≤ 1 keV if stable². The Jeans mass for a 1-keV noninteracting particle is $\sim 10^{12} M_\odot$, about the mass of a typical spiral galaxy including the nonluminous halo. We suggest here that the gravitino dominated universe can produce galaxies by gravitational instability while avoiding several observational difficulties associated with the neutrino dominated universe.

There is evidence that a considerable fraction of the mass in the Universe is nonbaryonic. Light element synthesis in the big bang requires that the density parameter³ $\Omega_b = \rho_b / \rho_{\text{crit}} < 0.014 H^{-2}$, where ρ_b is the present baryonic density, $\rho_{\text{crit}} = 11 \text{ keV cm}^{-3} H^{-2}$ is the closure density of the universe, and H is the Hubble parameter in units of $100 \text{ km s}^{-1} \text{ Mpc}^{-1}$ (observationally, $0.4 < H < 1$).

On the other hand, observations give a lower bound⁴⁻⁶ on the total density parameter $\Omega > 0.1$. On a galactic scale, there is also strong evidence that the mass in stars is considerably less than the mass of the nonluminous halo.

The present neutrino number density is $109 \text{ cm}^{-3} (T/2)^3$ per species. Because observationally the density parameter Ω cannot significantly exceed unity, the sum of the masses of all stable neutrino species is < 100 eV. Experimentally, the electron neutrino mass is < 50 eV, with one experiment indicating a non-zero mass⁷. Particles such as gravitinos which interact much more weakly than neutrinos decouple at a temperature T_d much higher than the neutrino decoupling temperature and long before many species have annihilated and heated (thereby increasing the number density of) the remaining interacting particles (including neutrinos). For $\Omega H^2 < 1$, the resulting upper limit on the mass of such particles (assuming two interacting helicity states) is $1.9 g(T_d) \text{ eV}$, where $g(T)$ is the effective number of interacting species including neutrinos. The standard particle physics model (QCD plus Weinberg-Salam with three quark and lepton generations) gives $g \approx 50$ above the quark deconfinement temperature of a few hundred MeV, growing slowly to $g \approx 100$ at $T \sim 100 \text{ GeV}$, with perhaps another factor of two growth due to supersymmetry. Therefore any such particle must be less massive than $\sim 1 \text{ keV}$. Here we consider the possibility that such particles dominate the Universe and, for definiteness, assume them to be gravitinos of mass $\sim 1 \text{ keV}$.

The scenarios for galaxy formation strongly depend on whether baryonic matter, neutrinos or gravitinos dominate the present Universe (see Fig. 1). Baryon condensations of galactic size are strongly damped during the radiation era by Compton drag (Silk damping)^{8,9}. For non-interacting particles of mass m ,

the maximum Jeans mass is given by^{10,11} $M_J \sim (M_{\text{Planck}})^3 / m^2$, which, for Friedmann cosmologies, is the mass within the horizon when the particles become nonrelativistic. The free streaming of dissipationless particles such as neutrinos or gravitinos destroys density perturbations on all scales smaller than the horizon until the particles become nonrelativistic. In particular, the proper free streaming distance travelled by a noninteracting particle with present momentum p_0 between time t and the present time t_0 is¹²

$$D(p_0, t) = R_0 \int_t^{t_0} dt v(t) / R(t)$$

where $R(t)$ is the scale factor of the universe and $v(t)$ is the instantaneous velocity of the particle with respect to a co-moving frame. We take the Jeans mass at time t to be the present mass of particles within a sphere of radius $D(p_0, t)$, with p_0 the characteristic momentum at the present time (ref 12, appendix).

The most important aspect of Fig. 1 is that for gravitinos the maximum Jeans mass $M_{Jg} \sim 10^{12} M_\odot$ while for neutrinos $M_{J\nu} \sim 10^{16} M_\odot$. Therefore gravitinos provide a natural scale size for galaxies, while the neutrino-dominated universe can form galaxies only by fragmentation of much larger gravitational condensations^{13,14}.

The linear growth of neutrino and gravitino perturbations, of masses $10^{16} M_\odot$ and $10^{12} M_\odot$ respectively, is illustrated in Fig. 2. The density contrast $\delta = \delta n / n$ is a gauge dependent quantity, and here we follow the standard treatment^{15,16} in time-orthogonal coordinates. Adiabatic perturbations larger than the horizon grow as $\delta \propto R^2$ in a radiation-dominated universe, while $\delta \propto R$ for nonrelativistic particles in a matter-dominated universe. Before matter (gravitino) domination, nonrelativistic gravitino perturbations with $M > M_{Jg}$ but smaller than the horizon can grow by at most a factor 2.5 (refs 17, 18), since once inside the horizon radiation oscillates and relativistic neutrinos free stream away. Thus limited growth in δ occurs for $M_{Jg} < M < M_{\text{eq}} = \text{horizon mass when matter domination first occurs} \approx 10^{16} (\Omega H^2)^{-2} M_\odot$.

If the initial perturbation spectrum is $\delta(M) \propto M^{-(3+n)/6}$, then in the matter dominated era $\delta(M)$ falls off steeply for $M < M_{Jg}$ due to free streaming of the relativistic gravitinos, is flattened with $n_{\text{eff}} \approx n - 4$ because of the effect just discussed for $M_{Jg} < M < M_{\text{eq}}$, and reflects the initial spectrum for $M > M_{\text{eq}}$. (This has been calculated in detail using the Boltzmann equation by

Fig. 1 The Jeans mass versus scale factor for a baryon, gravitino ($m = 1 \text{ keV}$), and neutrino ($m = 30 \text{ eV}$) dominated universe with $\Omega H^2 = 1$. Neutrino and gravitino perturbations with $M < M_J$ at any time are dissipated by free streaming.

Fig. 2 The growth of linear perturbations on mass scales $> M_J$ versus the scale factor of the universe ($\Omega H^2 = 1$) for noninteracting particles of mass 1 keV and 30 eV. The overall normalizations of these curves are arbitrary.

Bond *et al.*¹⁹) Finally, after hydrogen recombination, baryon fluctuations rapidly grow towards those of the gravitinos²⁰. Consequently, in the gravitino case, an initial adiabatic perturbation spectrum with $n \approx 1$ leads to the formation of galaxies of total mass $\sim 10^{12} M_\odot$, followed by baryon dissipation on galactic scales only²¹ (consistent with cooling constraints²²), with hierarchical clustering on scales between $\sim 10^{12}$ and $\sim 10^{16} M_\odot$. Observationally²²⁻²⁴, there is little variation in matter density from small clusters to superclusters, which in the absence of dissipation implies that clusters of all sizes collapsed roughly simultaneously—that δ is nearly constant between 10^{12} and $10^{16} M_\odot$. Such a spectrum ($n_{\text{eff}} \approx -2$) follows in the gravitino scenario from the plausible initial spectrum $n \approx 1-2$. Also, in contrast to the neutrino scenario where the formation of superclusters through dissipational pancake collapse^{13,14} precedes the formation of galaxies and must therefore have occurred at $z > 3$, in the gravitino scenario supercluster collapse follows galaxy formation and is dissipationless. This is consistent²⁵ with the observed²⁶ absence of clustering of Ly α absorption lines in quasar spectra and with the lack of extreme flattening in superclusters²⁷.

The nonluminous haloes of galaxies may also distinguish between the neutrino and gravitino hypotheses. If large spiral galaxies such as our own have haloes with radius ~ 100 kpc and $M/L \approx 50$, then there is not more than about a factor of two growth in the total/baryonic mass ratio from galactic to rich cluster scales. This is expected in the gravitino picture but not in the neutrino picture, where only $\sim 10\%$ of neutrinos are cooled enough to be captured by galaxies (A. Melott, and J. R. Bond, personal communications). It has indeed been suggested recently that the data are consistent with an approximately constant ratio of 7% baryonic to total mass on all scales larger than ~ 100 kpc (refs 22, 28). Finally, the phase space constraint^{29,30} on the mass of a fermionic halo particle is strongest for dwarf galaxies, for which preliminary analysis (S. Faber and D. Lin, in preparation) suggests this mass is at least several hundred eV.

We thank J. R. Bond, M. Davis, R. Giles, W. Mathews, A. Szalay, and especially S. Faber and D. Lin for helpful discussions, and the NSF and DOE for partial support. This is Lick Observatory Bulletin no. 931.

Discovery of 0.5-s oscillations in long flat top bursts from the Rapid Burster

Y. Tawara, S. Hayakawa, H. Kunieda, F. Makino & F. Nagase

Department of Astrophysics, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya, Japan

We report here a search for periodic emission of X rays from MXB1730-335 (the Rapid Burster, which is the most unusual X-ray burst source¹ out of about 30 other bursters) during the long flat top bursts². Two events from the 63 bursts showed clear peaks in the frequency power spectra at ~ 0.5 s in period. However, this is unlikely to be a pulsar period, because the periods of these two bursts are different.

The burst activity of the Rapid Burster was observed between 8 and 22 August 1979 with the X-ray astronomy satellite Hakucho. From 8 29 to 15 97 August (UT), bursts were exclusively long flat top ones. Owing to their high intensities and long durations, we were able to search for the periodicity of the X-ray intensity during these events.

We analysed 63 long flat top bursts of durations in the range 40-600 s. The power spectrum analysis was performed for the bin width of 93.75 ms, the shortest time bin available, over the frequency range 0.1-5.3 Hz. All but two bursts show no periodicity higher than statistical fluctuations. The upper limits of pulsed fractions thus obtained are 10% of the intensity during the flat tops of the bursts.

For the two long flat top bursts which occurred at A 19 h 04 min on 9 August and B 01 h 45 min on 11 August (UT), oscillations were discovered with the mean periods of 0.508 ± 0.001 s for burst A and 0.503 ± 0.001 s for burst B. Periods were determined both by the power spectrum analysis and by the folding analysis. Figure 1 shows the time profiles and the power spectra of these two events. The power spectra show clear peaks with the maximum power density of 23-24 times the average power density level of white noise, corresponding to a pulsed fraction of 30%. Statistical errors of these periods were estimated by the folding analysis. If we calculate the χ^2 defined as

$$\chi^2 = \sum_{k=1}^n (f_k(P) - \bar{f})^2 / s_k^2$$

where $f_k(p)$ is k th bin of the pulse profile folded with a trial period p , \bar{f} is the average of $f_k(p)$ over n total bins and s_k^2 is a variance of each bin, then a real period P_0 corresponds to the maximum χ^2 , $\chi^2(P_0) = \chi^2_{\text{max}}$. A statistical error of period

Table 1 Characteristics of two long flat top bursts showing 0.5-s oscillations

	A 9 August 19 h 04 min	B 11 August 1 h 45 min	C* 8-22 August
Burst			
Duration (s)	123	150	5-600
Peak luminosity† (erg s ⁻¹)	$(3.27 \pm 0.09) \times 10^{38}$	$(3.72 \pm 0.08) \times 10^{38}$	$(0.7-4.0) \times 10^{38}$
Total energy† (erg)	$(4.20 \pm 0.10) \times 10^{40}$	$(5.55 \pm 0.12) \times 10^{40}$	$(0.1-8.0) \times 10^{40}$

§ Obtained from dynamical power spectra for 24 s

ΔP is estimated as follows

$$\chi^2(P_0 \pm \Delta P) = \chi^2_{\max} - 1$$

The possibilities that these oscillations are of instrumental or geophysical origin can be excluded by the following tests (1) The period does not correspond to instrumental time constants and their harmonics that would cause the observed power spectrum peak (2) Oscillations with a period near 0.5 s are not found in the background data of 1.8 h obtained during this period of active bursts (3) The occurrence of the present oscillations have no correlation with geographical position and local time of the satellite. We therefore conclude that the observed oscillations are in the X-ray flux.

Characteristic properties of these two bursts and of the oscillations are summarized in Table 1. These two bursts occurred during the highest burst activity, the bursts during this period were of largest size, highest peak luminosity and had the hardest spectra¹. There are many bursts similar to the

oscillating events in size, luminosity and duration, but they show no oscillations. None of the 15 bursts observed between the two oscillating events A and B shows periodicity.

Several interesting properties can be noted for the observed oscillations. Figure 2 shows the power spectra of these two bursts every 24 s, where the statistical uncertainties of periods ΔP are 2 ms. Both a drift of the frequency and a variation of the pulsed fraction are clearly seen. For event A, the period of the maximum power density appears to have moved from 0.50 s to 0.52 s, the pulsed fraction increasing up to $40 \pm 10\%$, and the oscillation disappearing at ~ 20 s before the start of decay of the burst. Similar characteristics are observed for the other burst B as shown in Fig. 2.

Figure 3 shows the pulse profiles for energy band $L(1-9$ keV) and $H(9-22$ keV) respectively, obtained by folding the data of Fig. 2 Ab and Bc with periods of 0.511 s and 0.500 s for events A and B, respectively. The hardness ratios of the burst at the peak and the bottom of the folded profile are 0.296 ± 0.032 , 0.278 ± 0.046 respectively, thus they are the same within the

Fig. 1 The time profiles and the power spectra of the two long flat top bursts of 0.5 s oscillations. The time profiles start at A, 19 h 03 min 30 s on 9 August and B, 1 h 45 min 00 s on 11 August (UT) in 1979. The dashed line in the time profile of event A shows an increasing background level.

Fig. 2 The power spectra of events A and B for every 24 s, showing a drift of the period and/or phase of oscillations. Times indicated in each power spectrum in seconds are from 19 h 04 min 10 s on 9 August and 1 h 45 min 38 s on 11 August (UT), respectively

error limits. A nearly sinusoidal pulse profile is expected from the fact that the first higher harmonics is not significant in the power spectra shown in Fig. 1

As the 'rapid' bursts have been considered to be indicative of gravitational energy release by the accreting matter onto a neutron star³, the following two time scales of periodicity, within which the X-ray emission may be modulated, are conceivable (1) a stellar rotational period, (2) a keplerian period of matter orbiting around the neutron star. A 0.5-s period is an acceptable value in a pulsar period. However, a 1% change of the mean period for the two bursts separated by ~ 31 h, is too large to be accounted for by the rotating neutron star. The rotator model is also excluded by the facts that only two bursts show pulsations, that the oscillations disappear towards the end of the bursts, and that the period drifts during the burst.

The second possibility is related to a model proposed for the periodic oscillations observed in optical and X rays during outbursts from several dwarf novae such as SS Cyg (refs 4, 5)

The oscillations which are considered to take place in viscous accretion disks⁶ may also occur in an accreting neutron star with a period equal to the keplerian period at the magnetopause and then modulate the rate of accretion from the accretion disk to the neutron star. The radius of keplerian orbit with the period of 0.5 s is $\sim 10^8$ cm for a neutron star with the mass of $\sim 1 M_{\odot}$ and corresponds to the radius of the magnetopause for a magnetized neutron star with a magnetic field of $\sim 10^{12}$ G.

It is therefore conceivable that the modulation with a 0.5 s period in the matter supply from the region near the mag-

Fig. 3 The time profiles, folding the data shown in Fig. 2 A, b and B, c with periods of 0.511 s and 0.500 s, separately for L(1-9 keV) and H(9-22 keV) bands. The time, τ_L and τ_H , shown represents the data sampling time for the L and H bands, respectively

netopause to the surface of the neutron star results in the observed oscillations of the rapid burster. The fact that the hardness ratios of the bursts at the maximum and the minimum of the pulse are the same supports this possibility.

We thank the crew of the Hakucho satellite for providing observational data and to Professors Y. Tanaka and M. Matsuoka for their valuable comments.

A possible resurfacing mechanism for icy satellites

J. Klinger

Laboratoire de Glaciologie et Géophysique de l'Environnement,
38031 Grenoble Cedex, France

Photographs from Voyager Missions reveal a great variety of surface features for the icy satellites of Saturn¹. Mimas is covered with many old craters. Enceladus has a rather smooth surface with few and rather young craters. Some parts of Dione's surface have an important crater density, whereas other parts are relatively smooth. Thus some of Saturn's icy satellites seem to have undergone important surface modifications during their history while others did not. I suggest here that the irreversible phase transition between amorphous and cubic ice and similar phase transitions may provide a low energy resurfacing mechanism for these icy satellites.

To explain the resurfacing of Enceladus it has been suggested² that its interior may contain liquid water covered only by a thin crust of ice. For a given thickness of the crust, it is possible to estimate what the subsurface heat flux must be. For a surface temperature of 100 K, a liquid core temperature of 273 K and a heat conduction coefficient like that of normal hexagonal ice³ we obtain a heat flux in the order of magnitude of 0.1 W m^{-2} . This is comparable to the mean terrestrial heat flux ($\sim 0.063 \text{ W m}^{-2}$). If this heat flux has to be maintained permanently by tidal heating, the tidal dissipation must be at least $7 \times 10^{10} \text{ W}$ in the whole satellite. Peale *et al.*⁴ calculated the average volumetric tidal dissipation in Saturn's satellites. They found for Enceladus $2.2 \times 10^{-10} \text{ W m}^{-3}$. That corresponds to a total dissipation of $1.4 \times 10^7 \text{ W}$. So it seems difficult to maintain a liquid core by tidal heating and even more difficult to heat up a low temperature core and to melt it.

I now propose an alternative resurfacing mechanism that needs much less initial energy input. It has been shown^{5,6} that the irreversible phase transition of water ice that occurs between amorphous and cubic ice at $\sim 153 \text{ K}$ may influence the heat balance of comet nuclei. The same phase transition may in some cases be responsible for resurfacing of icy satellites. Suppose that the satellite has been condensed at temperatures sufficiently low so that the ice is in the amorphous state. As amorphous ice is a very poor heat conductor, we can assume that a large part of the heat dissipated in the interior of the icy body is used to heat it up. When in one part of the satellite the transition temperature is reached, the phase transition will start. The heat release during crystallization is about 100 J g^{-1} (ref. 7). This energy can be used to heat the neighbourhood. On the other hand the heat conduction coefficient of crystalline ice at the transition temperature seems to be about 10 times higher than that of amorphous ice³ and a growing part of the internally dissipated heat will be lost to the surface. These two mechanisms

are in competition. But as the crystallization of the amorphous ice will start in the interior the heat loss will be unimportant until the surface layers undergo the phase transition.

In the case of Enceladus the tidal dissipation calculated by Peale *et al.*⁴ is able to heat this body from 100 to 153 K in 7,000 Myr. This is evidently not realistic. But Ghormley⁷ found that amorphous ice condensed at 20 K and released 33 W g^{-1} during heating from 20 to 77 K and 92 W g^{-1} between 77 and 153 K. The heat release is smaller for ice condensed at higher temperatures. This heat will considerably speed up the process and only slight heating by tidal dissipation is necessary to initiate the temperature rise.

On the other hand, Yoder⁸ proposed that the eccentricity of Enceladus has been pumped to a higher value than the present one. This may produce some excess heating and allow a still more rapid heating from the orbital equilibrium temperature to the phase transition temperature. Evidently the mechanism described here may be combined with resurfacing mechanisms of very different nature.

Amorphous ice has a density between 1.1 and 0.94 g cm^{-3} depending on the condensation temperature⁵. During the phase transition nearly all water molecules are reoriented and the density decreases. This decrease in density may produce surface cracks and contribute to the smoothing of existing surface features.

If the heat transport to the surface due to conduction is not able to evacuate all the heat dissipated in the icy body, the internal temperature will continue to rise and might reach the transition temperature between cubic and hexagonal ice where a second resurfacing process may take place. A third resurfacing may take place when the melting temperature of hexagonal ice can be reached. When the heat loss to the surface becomes more important than the internal dissipation the satellite will cool down to the equilibrium temperature, in the case of Saturn's satellites to a temperature near 100 K. This cooling can take place after a partial or a complete resurfacing or after one or more resurfacing periods.

It is evident that similar mechanisms may apply when other materials undergo similar phase transitions. We know, for example, that the heat conduction coefficient of at least one clathrate hydrate is of the same order of magnitude and has a similar temperature dependence as amorphous substances⁹. We therefore suppose that such kind of effects will appear when clathrate hydrates reach their limits of stability.

According to Gaffney and Matson¹⁰, high pressure forms of ice may locally be produced during crater formation. Those forms are metastable at low pressures for temperatures that can be found on Jupiter's and Saturn's satellites. The lifetime of those polymorphs is evidently temperature dependent. Destruction of those ices may also contribute to a resurfacing. Gaffney and Matson suggest that icy satellites should be investigated by means of IR reflection spectroscopy. In fact, morphological studies of impact crater and other surface features combined with IR scanning reflection spectroscopy during future space missions could yield information about the chemical nature and the physical state of surface materials, on the chronology of surface smoothing, and the mechanisms involved. Those kinds of mechanism may occur on many satellites of the outer planets.

More quantitative work on the problem of the geological activity of icy satellites is planned in our laboratory. This work has been sponsored by INAG-ATP Planetologie grant 37-86.

Flare induced geomagnetic activity and orientation of the photospheric magnetic field

C. S. Wright & L. F. McNamara

Ionospheric Prediction Service, Australian Department of Science and Technology, Darlinghurst, New South Wales 2010, Australia

Attempts to determine which solar flares produce geomagnetic storms have focused attention on the importance of the direction of the magnetic field at the flare sites. Pudovkin *et al.*¹⁻³ have claimed that solar flares that occur above regions in which the photospheric magnetic fields have southward components produce geomagnetic storms whilst flares associated with northward magnetic fields do not. However, other studies have shown that geomagnetic storms are also highly correlated with energetic flares⁴, especially those accompanied by radio spectral type IV bursts⁵⁻⁸. McNamara⁸ suggested that these two sets of results were not reconcilable because they implied that nearly all type IV bursts were associated with flares with southward fields. Although this implication seemed unreasonable, recent evidence^{9,10} lends it some support. We have investigated the relationships between geomagnetic disturbances, flare energies and flare-site magnetic field directions for all large flares that occurred between 1968 and 1979. Contrary to the results of Dodson *et al.*¹⁰ we find no significant differences between the average energies of flares with northward, southward or east-west magnetic fields. Furthermore, although the inferred direction of the field at the site of a flare appears to control the geoefficiency of the flare to some extent, we find, contrary to Pudovkin *et al.*¹, that the relationship between geoefficiency and field direction is unclear.

Our study included 342 flares (with longitudes $\leq 70^\circ$) of importance 2 or greater that occurred between 1968 and 1979¹¹. Using the Mt Wilson and Kitt Peak magnetograms¹², we attempted to determine the photospheric magnetic field direction underlying the centroid of each flare under the assumption that the field was directed at right angles to the contours of magnetic intensity. Our procedure for inferring the field direction underlying the flare follows that of Pudovkin *et al.*¹. However, we make no assumptions concerning the relation between this direction and the true direction of the magnetic field within the flare site which lies above the photosphere in the chromosphere and base of the corona¹³ (Hereafter, unless otherwise stated, it is the inferred direction of the photospheric field that is implied in all discussion of the magnetic field direction at the flare site). In many cases the flare centroid was located above strongly curved contours and it was not possible to ascribe an accurate field direction. For this reason we categorized the directions into eight broad ranges (45° wide) centred on the eight cardinal directions N, NE, E, SE, S, SW, W and NW. Thus our field directions were defined with respect to the heliographic meridian of longitude at the flare site whereas Pudovkin *et al.*¹ defined their directions with respect to the projected orientation of the Earth's axis. We have compared our field directions with those determined by Pudovkin *et al.*¹ for all flares that were common to both studies and we found good agreement. In particular, nearly all flares that had northward and southward field components with respect to the Earth also had northward and southward components (respectively)

Fig. 1 The dependence of geomagnetic activity on the flare energy index. Each flare in our sample was grouped according to the magnitude of its energy index, I . The average value (\bar{A}_p) of the geomagnetic index, A_p , on the second and third days after the flares in each group was calculated. \bar{A}_p was then plotted against the average value of I for each group. The results for our entire sample of flares (●) are shown for which the magnitudes of the standard errors of the means are indicated by boxes. Also shown are the results (without error boxes) for flares in the periods 1969-76 (○) and 1977-79 (×). The mean background level of A_p is indicated by the horizontal broken line.

with respect to the Sun. Table 1 shows the distribution of the flares amongst the eight cardinal directions.

To estimate the relative energies of the flares in our sample we conceived a flare energy index, I , which is similar to the 'comprehensive flare index' (CFI) proposed by Dodson-Prince *et al.*⁴. We have introduced our own index because it is directly calculable from data to which we have ready access whereas the CFI is not. Our index takes into account flare characteristics that indicate high energy release^{13,14}, particularly those found by McNamara⁸ to be important in the flare-storm relationship. These were H α importance and intensity, X-ray class and radio spectral class. To each characteristic we attached a numerical weight in the manner shown in Table 2 and the value of the index for a given flare was then determined by summing the individual weights. Hence the least important flare in our sample, a 2F event with no radio or X-ray bursts, corresponds to a flare index of $I = 2$. The most important flare in our sample, a 3B event with X-class X-ray-ray burst, type II and strong type IV bursts, corresponds to an index $I = 15$. No X-ray data was available for 1968 so that I could not be computed for flares in that year. Also, there were a few flares in subsequent years for which I could not be computed due to incomplete data.

The level of geomagnetic activity following the flares in our sample was assessed by means of the method of superposed epochs which we applied to the daily geomagnetic index A_p . In agreement with Dodson-Prince *et al.*⁴ we found that A_p usually peaked 2-3 days after large flares. Hence to assess the geomagnetic importance of flares within any particular class we used the average value of A_p (\bar{A}_p) on the second and third days after the flares. The dependence of \bar{A}_p on the energy index, I , is shown in Fig. 1. The average level of geomagnetic activity increases slowly with I for flares with energy indices in the range $0 < I \leq 10$. However, when $I > 10$ the average level of geomagnetic activity increases rapidly with I . This is consistent with studies^{4,8} that show that very large flares nearly always produce geomagnetic storms. Figure 1 also shows that I preserves its identity over a long period of time since data for 1969-76 and 1977-79, when considered separately, define the same relationship between I and A_p . Therefore, we consider I to be a useful index with which to describe, semiquantitatively, the relative energy release of large solar flares.

Using the calculated values of I for all the flares in our sample, we were able to investigate the relative contributions

of flare energy release and magnetic field direction in the flare-storm relationship

First, we considered whether a relationship existed between energy release and flare-site field direction. For this purpose we calculated the average values of I for flares with northward, southward and east-west magnetic fields. The results are shown in Table 3. In addition to the flares in our sample we have considered the flares listed by Pudovkin *et al.*¹ Several cases are distinguished. Case 1 includes all flares described by Pudovkin *et al.*¹ for which I could be determined. All but three of these flares occurred between 1969 and 1970. In this case the subdivision of flares amongst field directions was made using the directions measured by Pudovkin *et al.*¹ Case 2 includes all flares in our sample that occurred during the same period (1969-70) and, in this case, the subdivision was made using our field directions. Case 3 includes all flares that occurred after this period, that is 1971-79, and case 4 includes our entire sample. The number of flares within each subdivision is indicated. The errors that appear against the average values of I are the standard errors of the means.

In case 1 the average value of I is significantly greater for flares with southward fields than for flares with northward fields (A similar result is obtained using the CFI of Dodson-Prince *et al.*⁴). This difference in average energies certainly would have given the flares with southward fields greater apparent geoefficiency and may partly explain the results of Pudovkin *et al.*

Table 2 Construction of flare energy index

Flare characteristic		Numerical weight
$H\alpha$ Importance,	2	2
	3	3
$H\alpha$ Intensity,	Faint	0
	Normal	1
	Bright	2
X-ray class,	No event	0
	C	1
	M	2
Radio type II,	X	4
	No event	0
	Event	2
Radio type IV,	No event	0
	$P < 100^*$	2
	$P \geq 100^*$	4

* P is the product of the intensity (1, 2 or 3) and the duration (in minutes) of the Type IV burst as listed in the radio spectral reports

*al.*¹ This also has been suggested by Dodson *et al.*¹⁰ who went further to argue, on the basis of the sample of flares used by Pudovkin *et al.*¹, that large solar flares are significantly more likely to occur over southward field regions. We suggest that this apparent bias may be due to selection effects as this sample did not include all flares of importance 2 or greater during 1967-70. Our results show no significant bias of this kind within the complete sample of flares (from the group reports¹¹) which occurred during the partially overlapping period 1969-70 (case 2). The same conclusion can be drawn from cases 3 and 4 which show that the number and the average energy of flares with southward fields do not differ significantly from the number and the average energy of flares with northward fields. These results hold even for the very largest flares. Of the flares in our sample for which $I \geq 12$, 15 had southward fields and 11 had northward fields. Of the flares for which $I \geq 8$, 34 had southward fields and 32 had northward fields. Thus our results do not support those of Dodson *et al.*¹⁰ Furthermore, even if flares with southward fields were more energetic than flares with northward fields during the period 1967-70 it is doubtful whether the magnitude of the bias (case 1) is sufficient to explain the results of Pudovkin *et al.*¹ This is clear from Fig. 1 which shows only a small difference in \bar{A}_p for flares with average indices of 5.1 and 9.3.

Next, we considered the geoefficiencies of flares of similar energies but with different field directions. Figure 2 shows the

Fig. 2 Same as Fig. 1 except the data (from our entire sample) have been subdivided according to the inferred magnetic field directions at the sites of the flares. Results for flares with northward (\times), southward (\circ) and east-west (\bullet) fields are shown. The magnitude of typical r.m.s. errors of the means is indicated.

dependence of \bar{A}_p on I when the inferred magnetic field direction at the flare site is taken into account. Three curves are presented, showing \bar{A}_p plotted against I for flares with northward (N, NE, NW), southward (S, SE, SW) and east-west (E, W) magnetic fields. The scatter in the data points is larger than in Fig. 1 due to the smaller sample sizes involved. We have attempted to fit curves of the form shown in Fig. 1 to the data for each field direction. For flares with northward and southward fields, curves of this form fit the data points quite well. For flares with east-west fields, a curve of this form does not fit well but is reasonably compatible with the data points shown (note the data points at $I \approx 3$ and $I \approx 10$).

Several features of Fig. 2 are worth noting.

- (1) When $I \leq 10$, the magnitude of \bar{A}_p for flares with southward fields only slightly exceeds the magnitude of \bar{A}_p produced by flares, of similar energy, with northward fields.
- (2) When $I \geq 10$, the magnitude of \bar{A}_p is significantly greater for flares with southward fields than for flares, of similar energy, with northward fields.
- (3) Flares with eastward or westward fields tend to produce higher values of \bar{A}_p than flares, of similar energy, with either northward or southward fields.

Hence, the geoefficiency of solar flares appears to depend on the direction of the magnetic fields at the sites of those flares. However, in contrast to the results of Pudovkin *et al.*¹, flares for which the inferred field direction is southward do not

Table 3 Dependence of average flare energy on field direction

Case	Field direction					
	Southward (S, SE, SW)		East-west		Northward (N, NE, NW)	
	No	Average I	No	Average I	No	Average I
1 Pudovkin <i>et al.</i> 1969-70	12	9.3 \pm 1.4	12	6.2 \pm 1.0	21	5.1 \pm 0.5
2 This study, 1969-70	18	6.7 \pm 0.9	19	6.2 \pm 0.7	36	5.5 \pm 0.5
3 This study, 1971-79	50	8.0 \pm 0.5	31	6.5 \pm 0.5	45	1.6 \pm 0.5
4 This study, 1969-79	68	7.7 \pm 0.5	50	6.4 \pm 0.4	81	6.7 \pm 0.4

have the highest geoefficiency. Clearly the relationship between field direction and geoefficiency needs reconsideration.

Pudovkin *et al.*¹⁻³ interpreted their results in terms of the well known association¹⁵⁻¹⁷ between geomagnetic disturbances and southward field in the solar wind. They argued that the orientation of the field within the flare site was preserved in the flare stream, thus accounting for the greater geoefficiency of flares for which the inferred field was southwards. However, the flare site is not confined to a narrow height range near the photosphere but extends upwards through the chromosphere, transition region and base of the corona.¹³ The field direction may vary substantially with height within the flare. In the case of strongly sheared fields, the difference between the true magnetic field direction in the chromosphere, for instance, and the inferred direction in the underlying photosphere may be as great as $\pm 90^\circ$ (ref. 13). Thus even if the field direction within the flare is preserved in the flare stream it may not resemble

the direction inferred from the photospheric intensity contours. However, a systematic relationship may exist between the direction of the field within the flare and the orientation of the underlying photospheric field. If so it may help to explain the results of Fig. 2.

We have found no evidence to support the suggestion¹⁰ that major flares are significantly more likely to occur over regions of southward magnetic field. Therefore, we feel that it is not possible to interpret the results of Pudovkin *et al.*¹ in this way. Our results (Fig. 2) indicate that the inferred direction of the magnetic field beneath the flare controls, to some extent, the geomagnetic effects of solar flares, particularly outstanding flares. However, the relationship between the inferred field direction and the geoefficiency is not as distinct as stated by Pudovkin *et al.*¹ and needs further investigation. We suggest that the true magnetic field direction within the flare site may be more relevant to the task of predicting geomagnetic effects of solar flares.

Direct imaging of travelling Rayleigh waves by stroboscopic X-ray topography

R. W. Whatmore

Plessey Research Ltd, Caswell, Towcester NN12 8EQ, UK

P. A. Goddard, B. K. Tanner & G. F. Clark

Department of Physics, Durham University, South Road, Durham DH1 3LE, UK

We report here the first successful experiments which exploit the time structure and single bunch mode of operation of the Daresbury Synchrotron Radiation Source (SRS). Rayleigh waves travelling on the surface of a piezoelectric crystal have been imaged by stroboscopic X-ray topography, in which the generation of the waves is synchronized with X rays emitted by the orbiting electrons in the storage ring. Interactions between the Rayleigh waves and microscopic crystalline defects have been observed and provide new insights into the factors affecting surface acoustic wave (SAW) device operation. It has been demonstrated that this novel technique has considerable potential for the study of periodic phenomena in crystals.

Piezoelectric SAW devices¹ are of great technological importance for high-frequency signal processing and filtering applications. Although the presence of crystallographic defects can have deleterious effects on the characteristics of these devices, there has been almost no study of the interactions between the Rayleigh waves and the defects concerned. Techniques such as electrostatic² and optical probes³ can be used to observe the waves, but these give no information concerning lattice strains or bulk crystal defects. Stroboscopic scanning electron microscopy has been applied to the study of piezoelectric Rayleigh waves⁴ but only surface defects and charges are imaged. X-ray topography⁵, a diffraction technique by which a two-dimensional map of the lattice strains in a crystal can be obtained, has been applied⁶ to reveal the average strain associated with a travelling Rayleigh wave but standard X-ray illumina-

tion gives no information about the periodic strains in the wave. Such strains can be revealed by generating standing waves although this gives information of limited relevance as most delay lines and filters operate by propagating travelling waves.

The unique time structure of X rays emitted from a storage ring can be exploited for stroboscopic X-ray topography in which the generation of the waves is synchronized with the illuminating pulses of radiation. Recent, independent experiments⁷ at Hamburg have demonstrated the feasibility of such a technique from studies of standing bulk waves in quartz.

Our experiments were performed with the Daresbury SRS running in the single bunch mode at 2 GeV, 1.8 mA with a lifetime in excess of 30 h, 97% of the synchrotron radiation was concentrated in a single pulse of width ~ 200 ps. A stroboscopic timing pulse was obtained from the SRS ring monitors. This 3.122 MHz square wave was frequency quadrupled, filtered and amplified to provide a 37.46 MHz, 15 V p/p sine wave to drive a 38 MHz LiNbO₃ television IF filter. White radiation X-ray topographs of the Y cut Z propagating LiNbO₃ crystal were taken using the multipurpose diffractometer at the

Fig. 1 Electrode configuration on the surface of the SAW device. The wave is generated in the interdigital transducer IDT and is transferred across the multistrip coupler MSC. It is detected at the receiving transducer R. W are the bonding wires, G marks the grain boundary visible in Figs 2 and 3.

Fig. 2 X-ray topograph taken of the Rayleigh waves without synchronization to the synchrotron radiation emission. The diffuse streaks correspond to the SAW strains, the fine curved lines to dislocations. The black line G is the sub-grain boundary indicated in Fig. 1. (The measured spacing of the standing waves ($33\ \mu\text{m}$) is reduced from the half wavelength value of $46.5\ \mu\text{m}$ by a factor of $\cos 45^\circ$ due to geometrical image distortion.) 0330 reflection, 45° Bragg angle. Specimen to plate distance, 35 mm.

SRS Topography Station⁸. LiNbO_3 has a space group $R3c$ and lattice parameters $a = 5.147\ \text{\AA}$ and $c = 13.856\ \text{\AA}$. In the hexagonal indices Y corresponds to $[01\bar{1}0]$ and Z to $[0001]$. For these experiments the $[01\bar{1}0]$ direction (normal to the crystal surface) was set at 45° to the incident X-ray beam. All topographs presented were taken in the Bragg geometry on Ilford L4 Nuclear Emulsion with exposure time of $\sim 1\ \text{h}$. The many topographs simultaneously recorded correspond to a large spot size, high spatial resolution back reflection Laue pattern. A Rayleigh wave was excited by an untuned interdigital transducer visible in the upper region of Fig. 1. The electric fields associated with it are transmitted laterally along a multi-strip coupler deposited on the surface. Thus a new acoustic wave is generated which propagates, parallel to the original wave, to the receiving transducer.

Figure 2 shows an X-ray topograph taken with the Rayleigh wave propagating but without the oscillator synchronized with the electron orbit frequency. Standing waves excited within the transducer are visible in the upper region and an increase in intensity due to the mean strain associated with the travelling wave emanating from it can be observed. Figure 3a shows part of a similar topograph taken with the driving signal phase locked to the synchrotron radiation emission as described above. A periodic array of dark and light bands is visible, an image of the strains in the crystal due to the travelling Rayleigh wave at an instant in the cycle. At $37.46\ \text{MHz}$, the wavelength of the acoustic waves is $93\ \mu\text{m}$ in LiNbO_3 and it is seen that, when the appropriate geometrical correction has been made for image distortion, the contrast pattern on the topographs corresponds to a period of a half wavelength. This occurs because strains

of either sense give rise to an increase in scattered intensity in white radiation topographs taken in the present conditions. Light areas, of intensity equal to the background, correspond to regions under very small strain at that instant of the propagating cycle. Detailed study of the visibility of the SAW in the many reflections recorded simultaneously on the photographic plate will enable the strain components to be determined.

Insertion of a time delay into the driving signal line enables the strains associated with different instants in the cycle to be examined. The result of inserting a 6 ns delay is shown in Fig. 3b. Light and dark areas have now interchanged, as is expected by moving back approximately a quarter of a cycle. Comparison of Fig. 3a with 3b reveals that the wavefronts are not always continuous throughout the cycle. At points X and Y, two 'dislocations' in the wavefronts are visible in Fig. 3a which are not present a quarter of a cycle later. Clearly some form of interaction is occurring periodically, a feature which cannot be detected other than by stroboscopic methods. Careful examination of the topographs reveals a phase shift of $\pi/2$ in the

Fig. 3 Stroboscopic X-ray topographs of travelling Rayleigh waves taken with the driving signal phase locked to the synchrotron radiation emission: a, no time delay; b, additional 6 ns time delay. The broad white line G corresponds again to the sub-grain boundary marked in Figs 1 and 2. $1\bar{3}21$ reflection predominant, 33° Bragg angle. Specimen to plate distance 20 mm. Projection of the diffraction vector is parallel to the crystal edge.

Fig. 4 Interaction of Rayleigh waves with lineal defects in the lower region of the multistrip coupler MSC. Note a phase shift of almost $\pi/2$ across the line RS. Same diffraction conditions as in Fig. 3. In both Figs 3 and 4, the wave propagates down the page.

acoustic wave along the multistrip coupler as predicted by Maerfeld⁹. In Fig. 4 we see a very strong interaction, present throughout the cycle, between a linear defect in the lower region of the multistrip coupler and the Rayleigh waves. The waves are phase shifted by about $\pi/2$ on crossing this defect, introducing another 'dislocation' into the images of the wavefronts. At present the nature of the defect has not been established.

Our experiments have established a totally new diagnostic tool for SAW device technology. Future studies will concentrate on Rayleigh wave propagation from transducers of varying configuration, the analysis of unwanted bulk modes excited by such transducers, the interactions with crystal lattice defects, the relation between diffracted intensity and wave strains, and the changes in SAW propagation as the frequency is increased. We have demonstrated that high-frequency stroboscopic X-ray scattering experiments are remarkably easy to implement with standard film recording techniques. In addition to X-ray topography, several diffraction experiments can now be envisaged to study rapid periodic phenomena in such diverse materials as thin films, ceramics, powders, fibres, polymers or even biological materials. The unique, extremely stable, time structure of the SRS running in single bunch mode has thus far not been the focus of other proposals for X-ray scattering experiments. Our present success and the availability to users of single bunch operation will hopefully stimulate many new experiments using these 200 ps width light pulses.

Financial support from SERC is acknowledged. We thank Dr P. J. Duke and Mr D. Warne for assistance in setting up these experiments.

Persistence of Sub-Saharan drought

Peter J. Lamb

Climatology Section, Illinois State Water Survey, Champaign, Illinois 61820, USA

The Sub-Saharan drought of the early 1970s attracted widespread attention. Particularly prominent was the suggestion that it was not likely to disappear in the near future, and could even persist into the next century¹⁻³. (The basis of this standpoint is reviewed in ref. 4.) In contrast, the post-1974 discussion of the Sub-Saharan climate has tended to the opinion that the drought ended by 1974 or 1975⁴⁻¹¹. That this may not be the case has been neglected. It was not investigated during several detailed studies of West African rainfall published since 1975¹²⁻¹⁶, because the data sets used terminated in 1974 or 1975, and is only weakly suggested by the World Meteorological Organization's annual summaries of significant meteorological events¹⁷. Strong claims that the drought continued beyond 1974 have been few, very brief, regionally focused, and qualitative¹⁸⁻²⁰. I therefore now provide a 1975-81 update of a Sub-Saharan rainfall index previously published for 1941-74²¹. This confirms the drought's persistence.

The Sub-Saharan rainfall index presented (Fig. 1) is the 1941-81 time series of the yearly average of the normalized April-October departures for 14-20 West African stations between 11 and 18°N west of 9°E. Its value for the year j is given by

$$\chi_j = \frac{1}{N_j} \sum_{i=1}^{N_j} \frac{r_{ij} - \bar{r}_i}{\sigma_i}$$

where r_{ij} is that year's April-October rainfall total at station i , \bar{r}_i and σ_i are respectively the mean and standard deviation of station i 's April-October rainfall for 1941-74, and N_j is the number of stations with complete records in year j . This index has never been evaluated before 1941 (ref. 21, Fig. 1; present Fig. 1) because only 6 of the 20 possible stations were operative then, one of which commenced in 1940. The remaining stations were established in 1941 (8), 1947 (1), 1950 (4) and 1951 (1). All 20 are located in Fig. 2 of ref. 21, which shows their adequate spatial distribution. These stations, which possess the most reliable and readily accessible records for the region, are those that appear in standard data publications²²⁻²⁶. Individual monthly station rainfall totals were obtained from these sources and various national and regional meteorological services. The April-October interval used includes both the July-September rainy season characteristic of the entire region, which on the average provides 80% of the annual rainfall²⁷, and the adjacent months that collectively contribute a further 17% (ref. 27). The continued adoption in this 1975-81 index update of the 1941-74 base period for \bar{r}_i and σ_i utilized in the original publication of the index for that period²¹, maintained the continuity of the time series in Fig. 1. For the proper use of a regional index of the present type, the rainfall departures must be statistically coherent throughout the region concerned. This has recently been strongly confirmed for Sub-Saharan West Africa^{13,15,16,18}. The statistical advantages of the particular index used here have been summarized by Kraus¹³.

The depiction of the index in Fig. 1 is complemented by the documentation in Table 1 of the consistency of the individual station departures for the years since the start of the aforementioned drought (1968), and also the dry years of the 1940s. These displays clearly suggest that the drought has not ended, despite the pronouncements to the contrary mentioned above⁴⁻¹¹. Although rainfall increased progressively from the especially severe 1972 drought year until 1975, this recovery did not reach even the 1941-74 mean value. Furthermore, it was immediately followed by a counterbalancing decrease in 1976-77. As a result, the 1977 rainfall was as deficient as that of 1972, and much more so that the other well-publicized severe drought years of the late 1960s and early 1970s (that is, 1968,

1970, 1971, 1973). While Subsaharan rainfall was clearly much greater in 1978 than a year earlier, this recovery also failed to reach the average value for 1941–74. Moreover the three most recent years have been characterized by a further progressive rainfall decline. This was sufficient to render 1979 and 1980 as dry as 1968 and 1970 and almost as rainfall deficient as 1971 and 1973, and to leave 1981 drier than all post-1967 years except for the very severe drought years of 1972 and 1977. The occurrence of the 1981 drought received little mention in the *Climatic Impact Assessment, Foreign Countries, 1981 Annual Summary* published by the United States' Center for Environmental Assessment Services (CEAS)²⁸; this organization now routinely monitors the globe's 'major anomalous meteorological events' and their 'adverse impacts'²⁸. Two of the seven 1975–81 years (1977 and 1981) also appear to have received substantially less rain than the better known drought years of the 1940s (Fig. 1). In addition, 1979 and 1980 were probably at least as dry as any year in the 1940s. Finally, it is thus clear that rainfall above the 1941–74 average has not returned to Subsaharan West Africa as a whole in the years since drought and famine made this region such a focus of attention in the early 1970s. This has extended the period since the last era of abundant rainfall (1950–58) to almost 25 yr.

The foregoing results have interesting implications. First, the suggestion that the Subsaharan drought was not likely to disappear in the near future^{1–3} has so far not been disproved. This fact, of course, does not constitute an endorsement of the basis of that prediction. Second, there is as yet no support for Faure and Gac's¹⁹ recent extrapolation-based projection of a gradual recovery from the present drought to more average rainfall during 1975–85. Third, the fact that the present drought has extended from 1968 to at least 1981 (14 yr), which is markedly longer than the three other distinct climatic epochs evident in Fig. 1 (1941–49, 1950–58, 1959–67; all of 9 yr duration), supports Kraus's¹³ findings that the Subsaharan rainfall record contains "unexpectedly long runs of wet or dry years" and that its droughts "tend to be rather persistent". This is notwithstanding Katz's²⁹ claim that the anomaly values possess "only a small degree of year-to-year persistence". Next, it should be emphasized that the occurrence of severe drought in 1977 and 1981 makes these years ideal candidates for case study investigations of the coincident (and presumably causal) tropical circulation anomalies in the manner already performed for 1972 (see ref. 10) and 1968 (see ref. 30). Finally, Glantz's³¹ 1977 belief that "with a return to above-mean rainfall levels, interest in dealing with (the) chronic (Sahelian) problems (of inadequate management practices and institutional arrangements revealed by the drought) will dissipate" now takes on added significance. The lack of publicity given to the continuation of the drought between 1975 and 1981 could well mean that such interest has

Fig. 1 1941–81 time series of the yearly average of the normalized rainfall departures (σ) for 14–20 Subsaharan stations west of 9°E. Kraus¹³, and Faure and Gac¹⁹ suggest that the largely dry epoch at the start of the time series (1941–49) commenced no more than a year or two earlier. The 1969 value of +0.06 is a correction of the +0.11 value published earlier²¹.

Table 1 April–October rainfall departure statistics for Subsaharan West Africa for 1968–81 and the drought years of 1941–49

Year	Fraction of stations with rainfall departure $\geq -1.0\sigma$ from 1941–74 mean	Fraction of stations with rainfall departure $\geq -0.6\sigma$ from 1941–74 mean	Average of all stations departures (σ)
1968	7/20	14/20	-0.78
1969	2/20	4/20	+0.06
1970	8/20	13/20	-0.72
1971	9/20	15/20	-0.88
1972	17/20	19/20	-1.39
1973	13/18	16/18	-0.91
1974	7/16	10/16	-0.60
1975	3/20	8/20	-0.27
1976	7/20	10/20	-0.62
1977	13/18	15/18	-1.42
1978	5/20	10/20	-0.42
1979	8/20	14/20	-0.70
1980	9/20	13/20	-0.80
1981	9/20	15/20	-1.00
1941	4/14	7/14	-0.67
1942	7/14	8/14	-0.63
1947	3/15	7/15	-0.46
1949	5/14	7/14	-0.58

evaporated even without a rainfall recovery. This may have been facilitated by the region's drought-induced population (human and animal) decline of the early 1970s reducing the socio-economic impact of the more recent deficient rainy seasons. The other alternatives—that the local infrastructure has dramatically improved and/or western aid has been suddenly beneficial—are more unlikely.^{9,31,32}

In view of the foregoing results and their implications, it is planned to update the present Subsaharan rainfall index towards the end of every calendar year.

Some of this material was first presented at the August 1981 Oxford Symposium on Variations in the Global Water Budget, with the aid of an award from the Legacies Fund of the Royal Meteorological Society and the encouragement of Stanley A. Changnon Jr. Grateful acknowledgment is also made of the data provided by West African regional and national meteorological services, and the assistance of P. Stone, W. Wendland, K. Hendrie and E. Kraus.

Late Palaeozoic Gondwana glaciation in Oman

J. H. Braakman*, B. K. Levell†, J. H. Martin†,

Late Carboniferous–early Permian sediments belonging to the Haushi Group in Oman have been considered to be partly of glacial origin^{1–3}. However, conclusive evidence of a continental glaciation has been lacking, and the extension of the late Palaeozoic Gondwana glaciation into the Arabian Peninsula has not been generally accepted⁴. During recent visits to outcrops of the Haushi Group in the Al Khilata area of the Huqf Massif (Fig. 1), we have found good exposures of striated pavements of Precambrian dolomite, which are directly overlain by diamictites of the Haushi Group (Fig. 2). This occurrence forms the strongest evidence so far for the presence of a continental glaciation in Oman during the late Palaeozoic.

Previous references to the occurrence of late Palaeozoic glacial sediments on the Arabian Peninsula have been summarized elsewhere^{5,6}. Roland⁵ describes the occurrence of striated and faceted pebbles and boulders of granites, gneisses and amphibolites in the Akbra shales of North Yemen and interprets them as dropstones from icebergs in a glaciomarine environment. Although no dating is mentioned, he considers the Akbra shales to be of late Palaeozoic age. McClure⁶ presents new evidence for a Stephanian to Sakmarian (late Carboniferous–early Permian) age of boulder beds in the Wajid Sandstone Formation at Khashm Khatmah and Jabal Umm Ghiran in Saudi Arabia (Fig. 1). He suggests that these boulder beds represent fluviially-reworked glacial deposits, but states, referring to the Arabian Peninsula as a whole: "Unfortunately, definitive indication of glaciation such as striated pavement and tillite is lacking".

In the context of a broader investigation into the sedimentology of the Haushi Group, exposures were studied in the outcrop area bordering the Huqf Massif (Fig. 1). Here the Haushi Group rests with an erosional unconformity on Precam-

Fig. 1 Location map: 1, Jabal Umm Ghiran; 2, Khashm Khatmah; 3, Al Khilata; 4, Haushi. (The Huqf Massif is shaded.)

brian formations of the Huqf Group. In the Al Khilata area this unconformity is well exposed in three different locations, forming a triangle of some 2 km². On the resistant surface of stromatolitic dolomites of the Huqf Group, parallel sets of striations and grooves (up to 35 cm wide and 10 cm deep) can be traced across the exposures, which are up to 30 m wide. Individual striae are up to 15 m long (Fig. 2). At this locality, 18 striae were measured (vector mean $45^\circ \pm 3^\circ$, vector magnitude 99.8%). In the other two localities, striae again have consistent mean azimuths of 45° although in one exposure a second set with an azimuth of 30° was observed. Direction of glacier movement could not be established from the striated pavements, but the consistent northeasterly foreset directions in fluviatile sandstones and conglomerates which erosively overlie the diamictite, suggest, in a simple palaeogeographical view, ice movement towards the north-east. The glacial sedimentary sequence appears to be onlapping onto the Huqf Massif, sediment transport being towards or along its margins. In two of the exposures a diamictite unit, with an average thickness of 4 m, rests directly on the striated dolomite (Fig. 2) and is therefore interpreted as a basal till. This diamictite is well exposed and correlatable over a distance of at least 1.4 km. Within a grey, fine-grained matrix it contains both igneous and sedimentary clasts. The sedimentary material consists of angular, centimetre-sized pieces of argillite and black chert (which may have been derived from the Precambrian Shuram Formation, outcropping 10 km south of Al Khilata) and fragments of dolomite probably derived from the local bedrock. The better-rounded pebbles and boulders of granite and other igneous rocks have not been related to any *in situ* occurrence in Oman. According to our present knowledge, no granites are present in surface or subsurface within a radius of 250 km of Al Khilata and hence the granite clasts are indicative of long-distance transport.

Further evidence for glacial deposition is found in several good exposures in the same area: sequences of rhythmically bedded or laminated fine sandstones and mudstones contain occasional outsize clasts (up to 240 cm), interpreted as dropstones from melting ice, floating on a body of standing water (Fig. 3a).

Table 1 Criteria for the identification of glacial deposits and their applicability in Oman

	Al Khilata	Subsurface
Abraded, striated bedrock surfaces	A	—
Stone-rich beds (diamictites)	A	A
Depositional fossil land forms	—	—
Dropstones	OP	A
Finely-graded stratification ('varves')	PP	A
Great thickness and extent of diamictites	—	PP
Association tillites/resedimented deposits	PP	OP
Variable clast lithology	A	A
Stones with wide range of shapes	A	A
Striated and faceted stones	OP	—
Clay-sized particles ('rock flour')	A	A
Fragile stones	OP	PP
Typical quartz grain textures	?	PP

A, abundant or well-defined; OP, occasionally present; PP, probably present; ? doubtful; —, not observed. Criteria after ref. 11.

Fig. 2 a, Parallel grooves on pavement of Precambrian dolomite, overlain by a 4 m-thick diamictite (Al Khlat area). Photograph taken towards NE. b, Striated pavement in same exposure. Photograph taken towards SW.

Fig. 3 a, Granite pebble and other dropstones in rhythmically bedded siltstones (Al Khlat area). b, Varved shale with dropstones from a cored well (South Oman).

Fig. 4 Palaeogeography of the Southern Hemisphere during the late Carboniferous (after ref. 13).

Interbedded with the dropstone-laminites, discontinuous bodies of diamictite and poorly-sorted sandy conglomerates occur, some of which contain striated dolomite boulders. These units are interpreted as sub-aqueous mud flows and debris flows. Although the general appearance of these diamictites is similar to that of the basal diamictite, stratigraphical relationships favour an interpretation as subaqueously redeposited glacial debris.

Without the presence of the sedimentary units described above, which show strong evidence of a glacial environment, it would be difficult to place the bulk of the Haushi Group sequences as exposed in the Al Khlat area in a glacial setting, as it consists mainly of cross-bedded sandstones and conglomerates of fluvial or fluvio-deltaic origin.

The age of the Haushi Group in the outcrop area has been well established by palynology. The diamictites and associated claystones from the Al Khlat exposures have yielded well-preserved palynomorph assemblages. The microflora consists largely of *Cristatisporites* sp., *Parasaccites* sp., *Potoniesporites* sp., *Punctatisporites* sp., *Vallatisporites* sp. and *Verrucosporites* sp. Less common constituents include bisaccate non-striate and bisaccate striate pollen and a distinctive species, *Ahrensia* sp. The assemblages resemble those illustrated by Kemp⁷ from the Permo-Carboniferous glacial sequences of Pakistan and Brazil, and display the general characteristics of those which are assigned a latest Carboniferous age by Balme⁸. A considerable amount of reworking of palynoflora might be expected in a glacial environment; however, the presence of multistriate pollen precludes a dating older than latest Carboniferous. A bioclastic limestone interval conformably overlying the sequence containing the boulder beds in the Haushi area (Fig. 1) has been assigned an age no younger than earliest Artinskian, probably Sakmarian (early Permian)⁹, thus confirming the late Carboniferous to early Permian age of the diamictite sequence in Al Khlat.

The new evidence presented here supports the concept of a glacial to periglacial origin for the lower part of the Haushi Group in Oman as accepted and used¹⁰ by Shell and PD Oman geologists since 1976, when the occurrence of varved shales with dropstones was reported in cored wells (Fig. 3b).

Table 1 summarizes the features which are generally considered to be indicative of a glaciation, showing which of these are found in the Haushi Group of Oman. The presence of the striated bedrock and the occurrence of dropstones are considered the most diagnostic characteristics of glacial activity¹¹.

The significance of this discovery in relation to the reconstruction of Gondwanaland during the late Palaeozoic still has to be assessed. Interpretations of the palaeolatitudes of Oman during this period vary considerably. Some reconstructions¹² show a low latitude (<40°) for Oman during this period, but a 1979 reconstruction by Scotese *et al.*¹³ shows Oman at about 50° during the late Carboniferous, which is a similar palaeolatitude to that assumed for the well-documented glacial deposits in South America, South Africa and Australia (Fig. 4). Therefore, the Permo-Carboniferous glaciation in Oman could serve as support for this reconstruction of Gondwana.

Finally, we have recently learned from Thiele (personal communication) that further evidence for a late Palaeozoic glaciation has been found in North Yemen in the form of striated bedrock (granite and gabbro), overlain by tillite belonging to the Akbra Formation¹⁴. Preliminary dating of this formation by palynology suggests an age younger than Namurian and probably Permian.

Internal company reports, using data of the more than 300 subsurface well penetrations of the Haushi Group have greatly contributed to our knowledge of these glacial deposits and stimulated further studies leading to this article. Special acknowledgement is made to the work of F. J. Winkler of Shell Expro, London. We thank Shell Research B. V., The Hague, and Petroleum Development Oman LLC for their permission to publish this paper, which appears with the approval of H.E. The Minister of Petroleum and Minerals of the Sultanate of Oman.

Volatile C₁–C₈ organic compounds in macroalgae

Jean K. Whelan, Martha E. Tarafa & John M. Hunt

Woods Hole Oceanographic Institution, Woods Hole, Massachusetts 02543, USA

Small amounts of C₁–C₈ volatile organic compounds were found in macroalgae in concentrations high enough (generally in the range of 1–400 times those in sediments) to suggest that the seaweeds are a source for some of the volatile organic compounds identified in recent marine sediments. The types of compounds identified^{1–4} include alkanes, alkenes, aldehydes, ketones, furans, and sulphides. Both the light hydrocarbons and the volatile functionalized organic compounds are believed to originate from living organisms and from both biological and chemical low-temperature reactions in the sediments. Understanding their mechanism of formation may help in deciphering the thermal and biological history of the sediments. Traces of some of these compounds can be produced from bacterial degradation of naturally occurring terpenoids⁵. We consider here their occurrence in algae.

Four species of seaweeds, *Ulva lactuca*, *Ascophyllum nodosum*, *Gracilaria tikvahiae* and *Hypnea musciformis* were

grown in 1,700-l aerated tanks using circulating seawater. The macroalgae (grown and maintained by J. Ryther of Woods Hole Oceanographic Institute) were selected because of their high productivity and ease of culturing. All the species studied were shallow water species often found in tidal zones. *U. lactuca* is found from the tropics to Newfoundland, *A. nodosum* from New Jersey northward, *G. tikvahiae* is from the tropics and *H. musciformis* grows from the tropics to the south coast of Massachusetts.

Algae samples were analysed by a modified head space technique which has been used to investigate volatile organic compounds in sediments³. The plants were disaggregated in a stainless steel blending assembly equipped with Teflon gaskets and a screw cover with a sampling septum. Each sample (20–40 g wet weight) of algae was placed in the blender with distilled degassed water leaving a 118 ml gas headspace. The blender was then placed inside a glove bag which was aspirated to exclude air and filled with helium. The vessel was sealed while inside the bag, its contents were blended at high speed for ~10 min, and then heated in a 90 °C water bath for 30 min. Samples were removed through the gas chromatography (GC) septum using a syringe and analysed by GC and GC-MS⁶. Degassed distilled water and the tank water in which the algae were grown were analysed as blanks. None of the compounds reported was detected in the blanks. Compound identification was based on a comparison of GC and GC-MS data with those of commercially available standards.

Amounts of compounds present in various species of algae are shown in Table 1. Except for the sulphides, none of these compounds have previously been reported in algae. Most of the compounds found in macroalgae also occur in surface marine sediments, but usually at lower levels (~0.1–100 ng per g)^{2,3,6}. The alkenes are found most frequently in marine sediments with an oxic sediment–water interface^{2,6}. They generally decrease to trace levels (<0.1 ng per g) in the top metre of sediment.

All species of algae in Table 1 contained *n*-pentane in concentrations >10 ng per g. No other pentane isomers were detected. The discovery that recent marine sediments generally have a low isopentane to *n*-pentane ratio could be partly explained by algal contributions of *n*-pentane⁷.

The aldehydes, ketones, furans, and sulphides of Table 1 are frequently found in marine sediments—for example, on the Walvis Bay Shelf, the Peru Shelf, and the Gulf of Maine^{2,3,6}. Their levels are in the range 0.1–100 ng per g in reducing sediments. However, they also occur sporadically in smaller amounts (0.01–10 ng per g) in sediments with oxic sediment–water interface, such as the Gulf of Maine and parts of the Peru Shelf. Some of these compounds have also been detected in more deeply buried (>100 m subbottom) sediments where the geothermal gradient is low enough that the compounds have not been exposed to temperatures >20 °C, such as DSDP sites 438 and 436 in the Japan Trench⁴.

It was previously proposed that some of the volatile organic compounds in sediments may be derived from terpene precursors which occur in marine organisms³. This work supports this concept. Algae provide a rich and diverse range of these terpenes^{8,9}. Large areas of these plants can be seen in surface ocean waters in many parts of the world. Even though the occurrence of various species of macroalgae in oceanic and coastal waters is patchy, the sinking of these large plants and their fragments would provide a way of rapidly delivering small, volatile molecules to the sediments with minimal water column biodegradation. Little is known about the contribution of macroalgae to organic matter on the deep sea floor¹⁰. It has been estimated that even in deep water, large particle sinking occurs in a matter of days¹¹. The macroalgae plant structure would prevent loss of these very volatile compounds and protect the more labile functional groups, such as the aldehydes, from biodegradation at the sediment–water interface where intense microbiological activity occurs¹². Because biological activity in sediments decreases rapidly with depth¹² burial of plant

fragments to depths of even a few centimetres could provide some protection of these molecules from biodegradation.

Although much recent work has concentrated on identifying larger molecules in macroalgae¹³, the smaller, more volatile components shown in Table 1 have been largely ignored. Certain compounds seem to be restricted to particular species: methyl-1, 3-cyclopentadiene in *H. musciformis* and three compounds in *G. tikvahiae* tentatively identified as 2-ethyl-cyclobutanol, cycloheptene, and 3-cycloheptene-1-one, based on a search of the NIH 30,000 mass spectral library¹⁴. An unusual feature of the latter two compounds is their mass spectral base peak at $m/z = 54$. The 3-cycloheptene-1-one occurs in very large amounts in *G. tikvahiae*. It is either very volatile or labile as the amount measured in material which had been frozen for several months had decreased from 1 mg per g to 3,100 ng per g. In frozen samples a similar decrease in concentration over time did not occur for other compounds shown in Table 1. The literature on natural products from red algae, of which *G. tikvahiae* is a member, does not report any structures comparable to the cycloheptene, 3-cycloheptene-1-one, or the ethyl cyclobutanol, although cycloheptadiene derivatives have been reported in brown algae¹⁵. These volatile compounds would be lost in normal isolation procedures which generally involve extraction with organic solvents.

Fig. 1 Mass spectra of compounds from *Gracilaria tikvahiae*. Tentative compound identification: a, 3-cycloheptene-1-one; b, cycloheptene; and c, ethylcyclobutanol.

* Preliminary identification.

† Compounds unstable in the analysis or without appropriate standards are shown as >.

‡ Total includes both dimethylsulphide and acetone.

Levels of alkanes, butanal, ethylcyclobutanol and dimethylsulphide in *G. tikvahiae* decreased in going from nutrient-enriched to nutrient-deprived cultures. However, concentrations of furans, ketones and the remaining aldehydes all increased. These differences seem to reflect a change in metabolism in the two cultures. It is known that lipid levels in organisms change in response to nutrient availability¹⁶, however, such changes have been observed only with lipids containing more than 15 carbon atoms. Our results show that changes also occur in the low molecular weight ranges.

Several species of phytoplankton (microalgae), *Thalassiosira* sp., *Gymnodinium* sp., *Emiliania huxleyi* and *Skellotenema costatum*, were analysed by the same methods as the macroalgae. Only one very volatile compound was detected which appeared to be a C₅ diene. This means that these phytoplankton cannot be directly contributing the compounds in Table 1 to sediments.

A variety of low molecular weight volatile alkanes, alkenes, ketones, aldehydes, furans, and sulphides have been found in macroalgae and the following conclusions may be made from their distribution: (1) Macroalgae are the probable source of some of these same compounds found in recent marine sediments. The low isopentane/*n*-pentane ratio of marine sediments could be partly caused by macroalgae. (2) Nutrient deprived macroalgae, such as *G. tikvahiae*, show a distinctly different volatile compound distribution from nutrient enriched algae. (3) Specific volatile compounds such as the cycloheptene and 3-cycloheptene-1-one in *G. tikvahiae* may be useful fingerprints in identification of algae. (4) Phytoplankton do not appear to be the source of volatile organic compounds in recent sediments.

Sterols are one of the most widely distributed group of organic compounds in the environment, ranging in geological age from Recent to Cretaceous, and are commonly found in soils and contemporary lake and marine sediments^{1–11}. The major sterols found in lake sediments are stenols, cholest-5-en-3 β -ol (C₂₇), 24-methylcholesta-5,22-dien-3 β -ol (C₂₈), 24-methylcholest-5-en-3 β -ol (C₂₈), 24-ethylcholesta-5,22-dien-3 β -ol (C₂₉) and 24-ethylcholest-5-en-3 β -ol (24-ethylcholesterol, C₂₉) and stanols, 5 α -cholestan-3 β -ol (C₂₇), 24-methyl-5 α -cholestan-3 β -ol (C₂₈) and 24-ethyl-5 α -cholestan-3 β -ol (C₂₉) (refs. 5–8, 10, 11). C₂₉ sterols are abundant in vascular plants, whereas C₂₇ sterols are often dominant in plankton. Thus C₂₉/C₂₇ sterol ratios are believed to be indicators both of allochthonous and autochthonous contributions of organic matter for lakes and of terrigenous sources of organic matter in marine environments^{5,7,8,10,11}. In the Antarctic, vascular plants are only found in the Antarctic Peninsula¹². Thus the sterol composition of Antarctic lake sediments is expected to be considerably different from those in the temperate and tropical zones. Here we report the first analyses of sterols in Antarctic lake sediments, which are found to contain high abundances of 24-ethylcholesterol. Such sterols must arise from blue-green and green algae in lakes and surrounding soils.

During 1976–77 and 1980–81 austral summers, sediments, epibenthic algae and moss were collected from the dry valleys of Victoria Land in the Antarctic (Fig. 1, Table 1). Characteristics of the dry valley lakes are described elsewhere^{13–17}. The lakes and ponds studied are all saline. The primary productivity measurements in Lakes Vanda and Bonney yielded low values of 29 and 31 mg C m⁻² day⁻¹, respectively¹³. Lake and pond bottom sediment samples were taken with stainless steel scoop, with polyvinyl chloride pipe (length, 340 mm; i.d., 89 mm) by a diver, or using a Kitahara-type water sampler. The algae were collected from the lakeshore, which is usually covered with epibenthic algae. These samples were transferred to a glass bottle or wrapped in a Teflon sheet and stored at temperatures below 0°C until analysis. Wet samples (10–300 g) were first homogenized with an Ace Homogenizer (10⁴ r.p.m., Nihon Seiki Co. Ltd), saponified with 0.5 M potassium hydroxide in methanol solution (80°C, 2 h) and centrifuged (1,800 g). Supernatants and residues were separately acidified, extracted with

ethyl acetate after the addition of distilled water, and then concentrated under reduced pressure at temperatures below 30°C.

Part (1–1/10) of the ethyl acetate extracts was evaporated to dryness, dissolved in 50- μ l benzene: ethyl acetate (1:1) and chromatographed on a silica gel column (180 \times 4 mm i.d., 100 mesh, 5% water). After elution of 2 column volumes of hexane, 3 column volumes of benzene: ethyl acetate (95:5) fractions were evaporated to dryness, dissolved in 100 μ l benzene and rechromatographed through a silica gel column impregnated with 3% potassium hydroxide (180 \times 4 mm i.d., 100 mesh). Fractions eluted with 3 column volumes of benzene: ethyl ether (1:1) were concentrated and trimethylsilylated (TMS) with 25% N,O-bis(trimethylsilyl)acetamide in acetonitrile solution (1 h, room temperature). The TMS ethers of sterols were determined using a combined Shimadzu LKB 9000 gas chromatograph-mass spectrometer (GC-MS). The GC-MS conditions are given on Table 1 legend.

The individual sterols were identified by comparison of their retention times and mass spectra with those of authentic compounds. Stenols and stanols were quantified by measuring peak height on the mass fragmentogram carried at *m/z* 129 and 215 which are characteristic to the TMS ethers of Δ^5 -stenols and 5 α -stanols, respectively^{3,5,6,18}. The detection limits of the sterols by mass fragmentography were \sim 0.1 ng. A blank run showed the presence of possible contaminants, but only minor amounts that would not affect the analytical results. To determine the analytical reliability, four replicate experiments using authentic compounds and a lake sediment were carried out and gave recoveries of cholest-5-en-3 β -ol, 24-methylcholest-5-en-3 β -ol and 24-ethylcholesterol of 83 (standard deviation, s.d., 11), 96 (s.d., 4.0) and 99% (s.d. 4.9%), respectively.

The contents of the six stenols and three stanols identified in the sediment samples range from 0.11 to 19 and 0.0 to 7.2 μ g per g dry sediment, respectively (Table 1). The amounts of sterols in the sediment from Don Juan Pond are extremely low, while those of Lakes Fryxell and Joyce are considerably higher. However, the amounts of stanols in the sediments from Lakes Vanda, Bonney and Joyce were extremely low. The ratios of sterol carbon to the total organic carbon contents differ considerably, ranging from 0.26 to 3.9×10^{-3} , comparable with those of contemporary lake sediments from the temperate zone (0.27 – 5.2×10^{-3})^{7,8,11}.

The sources of stanols in contemporary lake sediments in the temperate zone have been widely discussed elsewhere^{4,6–8}. Our stanol composition should therefore be attributed to the hydrogenation of stenols, algal materials as shown in Table 1 and/or subsequent preferential degradation of stenols relative to stanols, as in the case of the sediments in the temperate zone.

Surprisingly 24-ethylcholesterol is the dominant sterol in all these sediment samples. It is also the most prominent sterol in some soils and water samples from the dry valley areas (G.M.,

unpublished results) Thus the C₂₉/C₂₇ sterol ratios are high (1 4-7 2), and comparable with those of lake sediments from the temperate zone (0 48-8 5)^{6-8 10 11}, attributed to sterol inputs from vascular plants However, no vascular plants are present in the dry valley areas It is probable that there is preferential degradation in the sediments of C₂₇ relative to C₂₉ sterols, because the C₂₉/C₂₇ sterol ratios increase with increasing sediment depth in certain temperate lacustrine sediments^{6 8} However, a core sediment taken from Lake Fryxell (20 cm long) showed that the vertical changes in the C₂₉/C₂₇ ratios are small (G M, unpublished results) In addition the C₂₉/C₂₇ values of water samples through the depths from 5 4 to 65 9 m in Lake Vanda are very high (1 1-5 3, G M *et al*, unpublished results) Furthermore incubation experiments both in water and sediment have not revealed the marked changes in C₂₉/C₂₇ ratios (ref 8 and G M, unpublished results) Thus the effect of preferential degradation of C₂₇ sterols relative to C₂₉ sterols in cold dry valley lakes is small Therefore there seem to be at least three possible sources for these unusual distribution of sterols

(1) An input of aeolian dust, because small amounts of pollen have been found in the sediment cores taken by Dry Valley Drilling Project from the dry valley areas¹⁹ In addition Aeolian dusts are believed to be the principal sources of biological lipids of terrigenous materials in open ocean environments^{20 21} Normal alkanes are expected to be much more resistant to transformation than sterols in atmospheric transportation, because they are commonly found as the major constituents in atmospheric samples However, the sterol/*n*-alkane ratios calculated for aerosols from the tropical North Pacific (<0 063-<0 50)²¹ and atmospheric fallouts from the Tokyo area (0 034 and 0 13)^{22 23} are significantly lower than those of the sediment samples (0 55-750) of the dry valley areas (ref 24 and G M, unpublished results) In addition cholest-5-en-3β-ol is the most dominant sterol in these aerosols and atmospheric fallouts

These results showed that aeolian dust is not an important source for our sterols

(2) Glacial erosion of sedimentary rocks, because much of the sedimentary organic carbon in the Ross Sea is derived from the rocks being eroded by glaciers on the Antarctic continent²⁵ Very long-chain *n*-alkanoic acids found in soils from the dry valley areas are apparently originated from sedimentary rocks of Precambrian to Cretaceous ages²⁶ Stanol/stenol ratios of sedimentary rocks can be expected to be much higher than the living organisms, but these ratios of our sediment samples are rather lower than the contemporary lake sediments from common temperate lakes^{4 6-8} Further it was found that *n*-alkanes with the marked dominance of odd-carbon numbers and *n*-alkanoic acids with the great abundance of even-carbon numbers were not of ancient origin (ref 24, G M unpublished results) Thus sedimentary rocks are also unlikely sources of our sterols

(3) Biological sources, because many kinds of organisms, such as bacteria, fungi, blue-green and green algae, and mosses are found in the dry valley areas^{13 14 16 27} Certain bacteria contain sterols, but none with 24-ethylcholesterol as the most abundant sterol^{28 29} The principal sterol of fungi is ergosterol³⁰ Both organisms are therefore unlikely sources of our sterols Moss contains 24-methylcholest-5-en-3β-ol and 24-ethylcholesterol as their dominant sterols (Table 1), but the distribution of mosses in the areas studied is restricted, they only occur around Lake Fryxell in Taylor Valley Thus, mosses are also unlikely sources of the sterols in the sediments 24-Ethylcholesterol as the major sterol has been found in some Chlorophyceae³¹⁻³³, Xanthophyceae³¹ and Rhodophyceae³¹ *Synura petersenii*³⁴ and *Phormidium luridum*³⁵ also contain 24-ethylcholesterol as the most dominant sterol Our analytical results showed that 24-ethylcholesterol is the major sterols in epibenthic algae, mostly blue-green algae, which are widely distributed, collected from L-4 and L-12 ponds and Lake

Bonney Therefore algae, including green and blue-green algae, especially *Phormidium* spp are important sources of 24-ethylcholesterol in Antarctic dry valley lake sediments. In addition soil algae may contribute to the high abundances of C_{29} sterols in lake sediments²⁷

We thank the Japan Polar Research Association, Antarctic Division, DSIR, New Zealand, US NSF and US Navy for logistic support, Drs S Nakaya, T Cho, E Wada and G M Simons Jr and his research group for assistance in collecting samples, Professor H Fukushima for the identification of algae and Dr H Kanda for the identification of moss, and Drs K Ogura and T Itoh for useful suggestions

Direct demonstration of fluid secretion by glomerular renal tubules in a marine teleost

K. W. Beyenbach

Section of Physiology, Cornell University, Ithaca, New York 14853, USA and the Mt Desert Island Biological Laboratory, Salsbury Cove, Maine 04672, USA

The evidence for fluid secretion by the kidneys of teleosts is indirect¹⁻⁴. By using *in vitro* micropertusion of renal tubules⁵, we have observed fluid secretion in the proximal tubule of the winter flounder *Pseudopleuronectes americanus*. Unlike the isosmotic fluid transfer across most vertebrate proximal tubules, the secreted fluid in this teleost could be hyperosmotic to the bathing medium. More importantly, fluid secretion was not dependent on the transport of Mg, S or organic ions^{4,6}, but appeared to be driven by NaCl, the major solute in the secreted fluid. This mechanism of NaCl-dependent fluid secretion has been previously undetected because renal clearances showed the overall net reabsorption of NaCl and water^{4,7}.

P. americanus has a glomerular kidney containing 10,400 glomeruli on average and no aglomerular renal tubules have

Fig 1 Fluid secretion by proximal tubule. A 1.5-mm segment of a flounder proximal tubule (outer diameter 53 μ m, inner diameter 25 μ m) is shown in serial photographs. The tubule was held by two pipettes in aerated flounder Ringer's solution ($14 \pm 1^\circ\text{C}$) containing (mmol l⁻¹) NaCl 145, NaHCO₃ 20, KCl 5, Na₂HPO₄ 1.65, NaH₂PO₄ 0.3, MgSO₄ 1, CaCl₂ 1, and glucose 10, pH 7.4. The left end of the tubule was cannulated with a perfusion pipette containing light paraffin oil, the right end of the tubule opened into a holding pipette as shown in Fig 2. Perfusion filled the lumen with oil. When perfusion was stopped, epithelial fluid secretion fractionated the column of oil in the lumen and drove the flow of oil and secreted fluid towards the open end on the right $\times 65$.

been observed⁸. Renal clearance studies do not reveal net secretion of fluid^{4,7}. However, isolated proximal tubules suspended in Ringer's solution between two glass pipettes and filled with oil can be observed to secrete fluid as in Fig 1 where fluid secretion from bath to lumen displaced the oil from the lumen.

In subsequent studies of the characteristics of fluid secretion, the lumen was not filled with oil. Instead, one end of the tubule was closed by pulling it into a narrow glass pipette and the other end (open) was drawn into a collection pipette and sealed from the bath with uncured Sylgard, a viscous silicone resin (Fig 2). In these experimental conditions secreted fluid flowed from the open end of the isolated proximal segments at rates averaging 27.1 ± 3.2 pl per min per mm tubule length ($\bar{x} \pm s$, 19 collections, 12 tubules, 12 fish). Fluid secretion ranged from 9.8 to 56.6 pl min⁻¹ mm⁻¹ with no obvious correlation of secretion rate with the tubule's appearance. A conservative estimate for flounder proximal tubule length is 3 mm (ref. 8) which gives rates of *in vitro* fluid secretion (81 pl min⁻¹) and single nephron glomerular filtration (350-650 pl min⁻¹) within the same order of magnitude. For low filtration rates, proximal fluid secretion probably exceeds glomerular filtration as was observed in another glomerular flounder, *Paralichthys lethostigma*, in which urine flow rates were substantial (0.5 ml per kg per h) in the virtual absence of glomerular filtration (0.006 ml per kg per h)⁹.

The osmolalities of secreted fluid and the peritubular Ringer's were measured by freezing point depression (Clifton nanolitre osmometer) in nine experiments. In four experiments, secreted fluid was consistently isosmotic [292.1 ± 0.9 mOsm per kg H₂O ($\bar{x} \pm s$), $n = 8$ collections] to the bathing medium (290.5 ± 3.4 mOsm kg H₂O, $n = 13$). In the other five proximal segments, secreted fluid was hyperosmotic (318.4 ± 4.6 mOsm per kg H₂O, $n = 10$) to the bathing medium ($P < 0.001$). The highest osmolality in secreted fluid was 346.8 mOsm per kg H₂O. These data are consistent with the existence of two functionally distinct segments in flounder proximal tubules, as are thought to occur in the kidneys of marine fish¹⁰. Bulger and Trump have identified a proximal tubule I and a proximal tubule II in fixed

Fig 2 Collection of secreted fluid. Uncured Sylgard 124 (Dow Chemical) was used as a seal between the secreted fluid and the bath. Secreted fluid flowing from the tubule accumulated under oil and was collected every 30–40 min for analysis. Isolated segments of proximal tubules were usually between 1.2 and 2.0 mm long. Fluid secretion in any one tubule was rather constant for the duration of the experiment, in one case for as long as 18 h.

renal slices of another flounder, the English sole¹¹. In fixed renal slices of the winter flounder we have also observed two histologically distinct segments of the proximal tubule (unpublished observations). However, in the present study it was not possible to distinguish proximal tubules I and II during dissection and all data were pooled to describe the *in vitro* function of the flounder proximal tubule in general (Fig 3).

In 13 additional proximal tubule segments, the concentrations of Na, Cl, Mg and S (electron probe analysis measures the concentration of the element and not the ionic species) were measured in secreted fluid (SF), again in parallel with their corresponding concentrations in the peritubular bathing Ringer's (R)¹². Analysis of 22 SF/R sample pairs revealed that the Na concentration in SF was not significantly different from that in the bathing Ringer's, the 95% confidence interval of the Na SF/R ratio included unity (Fig 3). In contrast, the concentrations of Cl, Mg and S (SO_4^{2-} is probably secreted) in secreted fluid were significantly greater than in the bathing Ringer's. The 95% confidence intervals of these SF/R ratios did not include unity, but they were large, consistent with varying capacities for concentration in different segments of the proximal tubule. The ability of flounder renal tubules to generate and maintain transepithelial gradients for water and ions is consistent with previous measurements of their transepithelial electrical resistance¹³ which is higher ($22.3\text{--}53.0\ \Omega\text{cm}^2$) than that usually found in mammalian renal proximal tubules ($4.9\text{--}5.7\ \Omega\text{cm}^2$)¹⁴.

Previously, when evidence for fluid secretion was obtained in mammalian renal tubules⁶ and teleostean kidneys^{2,4,15}, it was thought that the secretion of organic acids⁶ or divalent ions created an osmotic driving force^{2,4,15}. However, in the isolated renal tubules described here, the presence of organic acids or divalent ions in the bathing medium was not necessary to support fluid secretion. Organic acids were not present in the flounder Ringer's solution used, and in four additional experiments in which MgSO_4 was deleted from the bathing medium fluid, secretion continued at rates ($18.2 \pm 3.1\ \text{pl min}^{-1}\text{mm}^{-1}$) that were indistinguishable from control (*t*-test, sample means).

The replacement of bath Na^+ with choline, a large cation, immediately and completely inhibited fluid secretion ($n=3$). Replacing choline-Ringer's with the original bathing medium (Na^+ -Ringer's) fully restored fluid secretion with the time course of the bath exchange ($<0.5\ \text{min}$). In contrast, when Na^+ in the bath was replaced with Li^+ , a small cation, fluid secretion continued in all tubules studied ($n=3$), but at progressively lower rates which paralleled the morphological deterioration of the tubule which occurred in Li^+ -Ringer's. Similarly, when Cl^- was replaced by a large anion (gluconate), fluid secretion immediately stopped ($n=4$). Fluid secretion returned to control rates on providing the original conditions in the bath. However, when bath Cl^- was replaced with a small substitute (Br^-), fluid secretion continued at rates indistinguishable from the control ($n=4$).

During this study some tubules were observed to constrict radially. The constrictions started as sharp invaginations of the basement membrane and extended radially towards the tubule

lumen. They occurred at single or multiple sites along the tubule. Some constrictions were sustained, others were periodic at about 3 cycles per minute. Peristalsis was not observed. Motion of axial cilia in the centre of the lumen was also occasionally seen. Solutions which stopped fluid secretion (Na^+ -free choline-Ringer's or Cl^- -free gluconate-Ringer's) also inhibited radial constrictions and ciliary motion. Solutions that restored fluid secretion (control bath) also restored tubule constrictions and ciliary motion. In tubules where radial constrictions and ciliary motion were not observed, the force of epithelial fluid secretion appeared to provide the hydrostatic pressure for axial flow. At present it is not clear whether myoepithelial cells or muscular layers^{10,16,17} are responsible for tubule constrictions. However, the constrictions were strong enough to move luminal fluid towards the open end of the tubule. Aiding axial flow in this manner might be a specialization of renal tubules that secrete fluid in glomerular kidneys having low filtration rates. In aglomerular kidneys radial constrictions might play an even greater part in the axial flow of luminal fluid.

Fig 3 Osmotic pressures and the concentrations in secreted fluid (SF) and peritubular Ringer's (R) expressed as the ratio SF/R. Mean values and their 95% confidence intervals are shown for two series of experiments. In the first, the osmotic pressure was measured by freezing point depression (Clifton Nanolitre Osmometer) in 18 SF and R sample pairs collected in experiments with nine proximal tubule segments. In the second, the concentrations of Na, Cl, Mg and S were measured in 22 SF/R sample pairs obtained in the study of 13 proximal tubule segments. Concentrations were measured in $100\text{--}200 \times 10^{-12}\ \text{l}$ liquid droplets against appropriate standards (STD) of the same volume by electron probe analysis (X-ray wavelength dispersive spectroscopy, JEOL 733 Superprobe). Correlation coefficients of STD curves (chemical concentration versus X-ray counts) were high for Na, 0.97 ± 0.02 , $n=9$ STD curves, for Cl, 0.96 ± 0.02 , $n=10$, for Mg, 0.994 ± 0.005 , $n=11$, and for S, 0.998 ± 0.001 , $n=11$. Deviations of STD curves from the origin ($\pm 3\ \text{mM}$) gave rise to experimental error only in the measurement of concentrations close to zero, such as the known $1\ \text{mM}$ Mg and S concentrations in the Ringer's. Some X-ray measurements gave values less than $0.3\ \text{mM}$ for the known $1\ \text{mM}$ MgSO_4 in the Ringer's. To prevent these measurements from increasing SF/R ratios, they were rounded up to $1\ \text{mM}$, but values greater than $1\ \text{mM}$ were not rounded down, hence SF/R ratios for Mg and S are underestimates of the true ratios. All samples, SF, R and STD, were stored in Ringer's-equilibrated (alternatively in light paraffin oil equilibrated with Ringer's) light paraffin oil until they were crystallized for electron probe analysis according to the method of Bonventre *et al*.¹² Evaporation into oil occurred at rates ranging from 0.4 to $0.9\ \text{pl min}^{-1}$ for the $1\text{--}3\ \text{nl}$ volumes handled in this study and introduced experimental error ($<12\%$). However, errors due to evaporation and sample dehydration were adjusted for by taking identical volumes of SF, R and STD of each tubule experiment together through all storage and dehydration steps. The use of more than one SF/R sample pair per tubule did not affect the statistical significance of the results.

The present study has provided the first collection and analysis of fluid secreted by a proximal tubule. Although vertebrate proximal tubules usually do not generate measurable transepithelial osmotic pressure differences¹⁸⁻²⁰ these results show that some proximal segments secrete hyperosmotic fluid, which may have a bearing on the previous *in vivo* observations of hyperosmotic urine in other marine teleosts^{21,22}. While the data confirm tubular secretion of Mg and S in marine fish, they do not support the hypothesis that fluid secretion is driven by Mg and S secretion alone⁴. A NaCl-dependent mechanism of fluid secretion is also present. This mechanism was unexpected because proximal fluid secretion in conjunction with glomerular filtration does not fit the present concept of hypo-osmotic regulation through the renal conservation of water.

This work was supported in part by NIH grant AM 26633 to K W B. and NSF grant DEB 7826821 and NIH grant S07-RR-05764 to the Mt Desert Island Biological Laboratory. I thank Dr B. Schmidt-Nielsen at MDIBL for the use of the Clifton nanolitre osmometer and Mrs Linda Phelps for secretarial assistance.

Absence of gonadotropin-releasing hormone receptors in human gonadal tissue

Richard N. Clayton

Department of Medicine, University of Birmingham, Edgbaston, Birmingham B15 2TH, UK

Ilopo T. Huhtaniemi

Department of Clinical Chemistry, University of Helsinki, SF-00290 Helsinki 29, Finland

The antifertility nature of the hypothalamic peptide gonadotropin releasing hormone (GnRH) and its synthetic agonist analogue (GnRH-A) has been repeatedly demonstrated in rodents, monkeys and humans (see ref. 1 for review). In all species studied, this action of GnRH was initially attributed to 'desensitization' of gonadal steroidogenesis due to loss of gonadotropin receptors in the testis and ovary, induced by high circulating levels of endogenous gonadotropins achieved following repeated administration of GnRH or GnRH-A²⁻⁵. Recently, an additional, direct inhibitory action of these peptides on ovarian granulosa^{6,7} and luteal⁸⁻¹⁰ and testicular Leydig¹¹⁻¹³ cells has been defined. This direct inhibition of gonadal steroidogenesis is mediated through specific high-affinity GnRH receptors in the respective target tissues^{8,9,12,14}. These receptors exhibit identical characteristics to GnRH receptors (GnRH-R)

in rodent anterior pituitary tissue^{9,12,14,15}. In the search for a naturally occurring ligand for gonadal GnRH-R, a biologically active 'GnRH-like' peptide has been isolated from rat ovary¹⁶ and testis^{17,18}, and from monkey testis interstitial fluid¹⁸. These findings suggest the production in rodent gonads of a GnRH-like peptide which, following interaction with gonadal GnRH-R, serves as a local modulator of steroidogenesis, and hence of reproductive capacity. If a similar situation exists in humans, GnRH-R should be detectable also in the human testis and ovary. We report here that we have been unable to detect any binding of radiolabelled GnRH-A to human corpus luteum or testis, or to the monkey testis. In contrast, GnRH-R were detected in adult and fetal human anterior pituitary tissue. Thus, we suggest that a direct inhibitory action of GnRH on primate reproductive function is unlikely. Furthermore, this important species difference highlights the need for a re-evaluation of certain rodent models designed to investigate primate, and especially human, reproductive physiology.

An area of considerable interest in reproductive biology concerns the apparently paradoxical antifertility nature of the natural hypothalamic-hypophysiotrophic hormone GnRH, responsible for the neural coordination of fertility. When administered to either laboratory animals or humans, either continuously or intermittently in high dosage, GnRH or its longer-acting agonist analogue (GnRH-A) interrupt normal cyclical ovarian activity, terminate established pregnancy, and inhibit testicular testosterone production and spermatogenesis (for review see ref. 1). In rodents, this inhibitory activity of GnRH is partly due to a direct action on ovarian and testicular steroidogenic cells. Recently, we and others (see ref. 14 for review) have reported that this extrapituitary action of GnRH and GnRH-A is mediated through specific receptor sites for the hormone either in the respective target cells, or in their cell membrane preparations.

To determine the presence of GnRH-R in primate gonadal tissue, we have used identical methods to those applied to measure rodent gonadal GnRH receptors. We used as the radioligand the iodinated GnRH agonist ¹²⁵I-GnRH-A¹⁴ which binds exclusively to high-affinity GnRH receptors in rat pituitary and gonads. Using this radioreceptor assay we have detected specific binding of the GnRH analogue to anterior pituitary membrane preparations from cadaver human glands (Table 1), despite the fact that these were removed 24-36 h postmortem at routine autopsy, and then stored at -70 °C before the assay. As considerable loss of GnRH receptors may have occurred during the time from death to freezing of the tissue, the antemortem content of pituitary GnRH receptors was probably considerably greater. We have been unable to obtain any fresh normal human pituitary tissue, although two samples of freshly obtained human pituitary adenomatous tissue were examined, neither of which contained GnRH-R (Table 1). One of these was a mixed acidophil chromophobe adenoma from a patient with acromegaly (growth hormone-secreting tumour), while the other specimen was a chromophobe adenoma secreting large quantities of prolactin. GnRH receptors were also detectable in homogenates from single human fetal pituitary glands obtained either from prostaglandin-induced abortions or at hysterotomy (Table 1). In the case of the former specimens, intra-uterine fetal death occurred 12-20 h before sample collection. However, when rat pituitaries were either collected and snap-frozen immediately after decapitation, or analysed without previous freezing and thawing, the binding of the ¹²⁵I-GnRH-A was much greater (Table 1). As this radioreceptor assay allowed detection of GnRH-R in human pituitary tissue obtained many hours after death, we used it as a method for measuring GnRH-R in fresh human gonadal tissue obtained at operation and frozen immediately. Before the radioreceptor assay, all gonadal tissues were treated in an identical manner to the human pituitaries.

There was no specific uptake of ¹²⁵I-GnRH-A by membranes prepared from corpora lutea obtained at various stages from the mid- to late-luteal phase of the menstrual cycle from six

Cadaver human pituitary (cadaver pit) tissue was obtained, from routine autopsy for non-pituitary-related disease, between 24 and 36 h post mortem, and snap-frozen following separation of the neurohypophysis. Human pituitary adenoma tissue was obtained at hypophysectomy and immediately snap-frozen in liquid nitrogen (the predominant histological staining pattern is indicated). Human fetal pituitaries were obtained after prostaglandin-induced abortion (*), or hysterotomy (†) and snap-frozen as soon as they were removed from the abortuses. Their sex and approximate gestational age are indicated in parentheses. Male rat pituitaries (Sprague-Dawley rats) were obtained immediately after decapitation and analysed without previous freezing (§), or were snap-frozen then thawed immediately before assay (‡). After snap-freezing all tissue was stored at -70°C for 1–4 weeks before assay, this does not result in any loss of rat pituitary GnRH-R¹⁴. Membrane preparations from the adult human pituitaries were prepared by homogenization (in an Ultra-Turax homogenizer) of the minced tissue in 10 mM Tris-HCl pH 7.5 containing 1 mM dithiothreitol (DTT). After initial centrifugation at 1,000g for 10 min (in a Sorval RC5B centrifuge), the membranes were precipitated from the supernatant by centrifugation at 25,000g for 30 min. The membrane pellet was re-homogenized in a small volume (1–2 ml) of 10 mM Tris-HCl and filtered through nylon gauze before use in the radioreceptor assay. All preparative procedures were performed at 4°C . Individual human fetal and rat pituitaries were homogenized, on ice, in 0.5 ml of 10 mM Tris-HCl and an aliquot of the unfractionated homogenate used for GnRH-R analysis. 100 μl of membrane or homogenate preparation were incubated with 100 μl of ^{125}I -GnRH-A ($1\text{--}3 \times 10^{-11}\text{ M}$) with (NSB, nonspecific binding) or without (total binding, Bo) a 1,000-fold excess of unlabelled GnRH-A in a total volume of 300 μl of assay buffer (10 mM Tris-HCl, 1 mM DTT, 0.1% bovine serum albumin, BSA) at 4°C for 90 min. The reaction was stopped by dilution (15-fold) with phosphate-buffered saline (PBS, pH 7.5) and the membrane fragments were separated (under vacuum) by filtration, through Whatman GF/C glass fibre filters, pre-soaked in 1% BSA to reduce nonspecific binding. After washing with 20 ml PBS, the filters were dried and counted in a γ -spectrometer with a counting efficiency of 60%. Specific binding (SB) = Bo - NSB and is expressed as a percentage (SB/T × 100) of total bindable counts added (maximum possible binding of ^{125}I GnRH-A = 50% of added c p m). Samples having the same total c p m were analysed in the same radioreceptor assay, a positive rat pituitary control was used in each assay. Values shown are the mean ± s.e., the number of replicates is shown in parentheses. Differences between Bo and NSB counts for each sample were analysed by unpaired Student's *t*-test and were considered significant if $P < 0.05$. ND, $P > 0.05$. On this basis, all human cadaver pituitary samples exhibited specific ^{125}I -GnRH-A binding. The average minimum significant difference between Bo and NSB counts (defined as 2 s.d. below the mean of Bo replicates) was $\sim 175\text{ c p m}$.

a, Human corpora lutea were individually excised as discrete tissue, without surrounding ovarian stroma, during laparotomy for either tubal reconstructive surgery, hysterectomy for uterine myoma, or endometriosis. Corpora lutea were obtained from the mid-late luteal phase of the menstrual cycle, the patients had not received any hormonal treatment in the 6 months before surgery. Corpus luteum tissue was immediately rinsed in ice-cold PBS, pH 7.4 to remove any adherent blood clot, snap-frozen in liquid nitrogen without further processing, then stored at -70°C for 1–4 weeks before assay. When required for assay, ovarian membranes were prepared from the frozen tissue as described in Table 1 legend **b**. As in **a** except that membranes were prepared from freshly obtained corpora lutea within 40 min of their removal from patients, without freezing or storage of the tissue, and assayed immediately. **c**, Rat ovaries were obtained from adult female animals at random stages of their oestrous cycles (random cycles) and from 25-day-old immature females treated with 50 IU of PMSG (pregnant mare serum gonadotropin, Organon) followed 5 days later by 25 IU of HCG and were killed 3 days later. These ovaries consist predominantly of luteinized follicles (luteinized ovaries). Rat ovarian tissue was frozen and thawed in the same way as for human tissue. Membrane preparations were prepared, incubated with ^{125}I -GnRH-A and the results expressed as described for Table 1. The common total c p m indicates that all tissues were analysed in the same assay, each of which incorporated positive rat ovarian membrane and pituitary homogenate controls. The average minimum significant difference between Bo and NSB counts was $\sim 170\text{ c p m}$.

Human testes were obtained from 60–80-yr-old patients at orchidectomy representing primary treatment for prostatic carcinoma. None had received previous hormone therapy with oestrogen. Monkey (*Macaca fascicularis*) testes were obtained from healthy adult animals during orchidectomy for experimental purposes. The testes were immediately snap-frozen in liquid nitrogen, without processing, and stored at -70°C for 1–4 weeks before membrane preparation and analysis. Testes from adult rats were frozen and stored in the same way as the primate specimens. Membrane preparations were prepared and incubated with ^{125}I -GnRH-A as described for Table 1. The average minimum detectable difference between Bo and NSB counts was ~ 130 c p m (2 s.d. less than the mean Bo).

individuals (Table 2), despite the presence of more membrane protein than for human cadaver anterior pituitary tissue. Fresh, unfrozen human corpora lutea analysed immediately after removal from the patients, were also devoid of GnRH receptors (Table 2). Thus, it is unlikely that the procedure of freezing and storage destroyed GnRH-R. Additionally, membrane preparations from whole, pre-menopausal human ovaries were devoid of GnRH receptors (data not shown), while identical membrane preparations from either fully luteinized rat ovaries or ovaries obtained from rats at random stages of their oestrous cycles contained many GnRH receptors. In each assay containing human ovarian tissue, at least one rat ovarian preparation and one rat pituitary homogenate preparation were included as positive controls. That the human corpus luteum membranes contained steroidogenic tissue was indicated by the presence of luteinizing hormone (LH) receptors, identified by binding of ^{125}I -HCG (human chorionic gonadotropin), in an aliquot of the preparation (data not shown).

Human and monkey testis membrane preparations also did not appear to interact with the labelled GnRH analogue (Table 3). Five different testicular preparations, obtained at orchidectomy performed as primary treatment for prostatic carcinoma, were all negative (Table 3). None of these patients had received previous hormonal (oestrogen) therapy. Similarly, no ^{125}I -GnRH-A binding was demonstrable in testis membrane preparations from three adult monkeys, obtained at orchidectomy (Table 3). Because the primate tissue had been rapidly frozen on removal, no attempt was made to separate the seminiferous tubules, which have no GnRH receptors, from the interstitial tissue, which in the rat is the only compartment exhibiting GnRH-R¹⁹. However, in one experiment in which fresh human testis was enzymatically dispersed to yield predominantly Leydig cells, there was no detectable GnRH binding, while an identical interstitial cell preparation from fresh rat testes was positive. In addition, the four rat testis membrane preparations, which were positive for GnRH-R (Table 3) comprised both tubular and interstitial cell elements as they had been stored and were prepared in an identical manner to the human samples. As with the human corpora lutea, human and monkey membrane preparations contained Leydig cell elements as evidenced by the presence of ^{125}I -HCG binding.

Thus, we have been unable to demonstrate the presence of any GnRH receptors in human corpora lutea using the most sensitive method available for detection of GnRH-R in pituitary and gonadal tissues. It is possible that the concentration of GnRH-R in human gonads is so low as to be unmeasurable by these techniques, but this seems unlikely. Indeed, using very similar methodology, Asch *et al.*²⁰ were unable to detect any GnRH analogue binding in monkey corpora lutea. Further-

more, they failed to show any effect of a GnRH agonist on progesterone production by acutely dispersed monkey luteal cells *in vitro*²¹. Similarly, human granulosa cell steroidogenesis *in vitro* was unaffected by either GnRH or an agonist analogue²². Although there has been one report²³ of direct inhibition of progesterone production for human granulosa cultured in the presence of a GnRH agonist analogue, this did not occur until after 96 h in culture. Further, the granulosa cells were exposed to concentrations of exogenous gonadotropin higher than that to which they would be exposed *in vivo* and this might alter their steroidogenic response pattern. In contrast, the inhibitory effects of GnRH peptides on steroidogenesis are observed immediately when rat luteal cells^{8,10}, rat granulosa cells^{6,7}, and porcine granulosa cells²⁴ are similarly incubated with GnRH or GnRH-A *in vitro*. Therefore, in the human and non-human primate it seems unlikely that the antifertility effect of this group of peptides involves a direct gonadal site of action. A similar conclusion might also apply to the mouse, as in this species no GnRH effect on Leydig cell function can be demonstrated *in vitro* and receptors for this peptide are also absent²⁵. It is possible that the laboratory rat is not representative of other species in respect of the direct gonadal effect of GnRH. Hence data from such studies in rats may not be applicable to primates. Specifically, we infer, from the data reported here, that human gonadal tissue may not produce any 'GnRH-like' material acting as an intragonadal modulator of reproductive function.

We thank the gynaecologists in Birmingham, Oulu and Helsinki for providing us with human ovarian tissue, and the various surgeons for providing the human testis specimens. This work was supported by grants from the MRC (to R.N.C.), the Finnish Academy (to I.T.H.) and the British Council Academic Links and Interchange Scheme (R.N.C. and I.T.H.).

A fragment of the SV40 large T-antigen gene transforms

Christine E. Clayton*, David Murphy, Michael Lovett† & Peter W. J. Rigby

Cancer Research Campaign, Eukaryotic Molecular Genetics Research Group, Department of Biochemistry, Imperial College of Science and Technology, London SW7 2AZ, UK

SV40-transformed cells retain and express all the sequences encoding large T antigen¹; this protein, in its entirety, appears to be essential for transformation^{1,2}. We have isolated³ a segment of integrated viral DNA (SV3T3-20-G) which encodes only the N-terminal half of T antigen but is capable of transforming rat fibroblasts. SV3T3-20-G-transformed cells synthesize a truncated T antigen of apparent molecular weight (MW) 48,000. The sequence of the virus-host junction shows that this protein is partially encoded by the flanking mouse DNA and suggests that the SV40 DNA has integrated next to a mouse gene. The mouse DNA segment of SV3T3-20-G is not required for transformation although transcription of these flanking sequences may be activated by the insertion of viral DNA.

The SV40 early transcription unit is transcribed in productively infected permissive cells into two mRNAs with identical 5' and 3' termini but different splices² (Fig. 1). The larger, 2.6 kilobase (kb) mRNA encodes small t antigen, a protein of apparent MW 17,000 which is not essential for transformation⁴⁻⁶ but which may, in some circumstances, have an enhancing role^{1,7,8}. The smaller, 2.3 kb mRNA encodes large T antigen, a protein of apparent MW 94,000 which is found predominantly in the nuclei of transformed cells and is essential for transformation^{1,2}. This protein has many functions⁹⁻²¹ but it is not clear which of its functions is directly involved in the transformation of non-permissive cells.

SV3T3-20-G is a segment of integrated viral DNA cloned from the genome of the SV3T3 C120 line of SV40-transformed BALB/c 3T3 cells³. This 8.5 kb *EcoRI* fragment (Fig. 1) contains 3.3 kb of viral DNA and 5.2 kb of mouse DNA, which includes a sequence element present many times in the mouse genome (P. Brickell, D. S. Latchman and P. W. J. R., unpublished data). The viral DNA segment extends from the *EcoRI* site (nucleotide 1,782; according to the system of ref. 2) through the 5' half of the late transcription unit and the origin of DNA replication and into the 5' half of the early transcription unit. The viral DNA is interrupted by a junction with cellular DNA located at the beginning of the region in which the *tsA* mutations map²². It thus lacks many of the viral sequences thought to be essential for transformation^{1,2}. We were therefore surprised to find that when pSV3T3-20-G (the SV3T3-20-G *EcoRI* fragment cloned into the *EcoRI* site of pAT153) was introduced into rat-1 cells by calcium phosphate-mediated DNA transfection^{23,24}, foci of morphologically transformed cells arose (Fig. 2) at a frequency of 5 per μg DNA per 10^6 cells, a frequency $\sim 1\%$ of that obtained with intact SV40 DNA²³.

* Present addresses: Department of Biochemistry, Stanford University Medical Center, Stanford, California 94305, USA; † Department of Pediatrics, University of California Medical School, San Francisco, California 94143, USA.

Fig. 1 Structures of pSV3T3-20-G and recombinants derived from it. At the top is shown the restriction map of SV40 DNA², linearized at the single *EcoRI* site. *HindIII* sites are marked †; the double-headed arrow indicates the *HindIII* fragment in which most *tsA* mutations map²². Also shown are the structures of the two early mRNAs found in productively infected permissive cells². \square , Translated sequences; \square , untranslated sequences; \sim , splices. The map of SV3T3-20-G is adapted from ref. 3; *XbaI* sites are marked \times . \blacksquare , SV40 DNA; \square , mouse DNA; --- , vector (pAT153) DNA. The two RNAs shown below are transcribed from the SV40 early promoter of this template (ref. 27 and M.L. and P.W.J.R., unpublished data). pSV3T3-20-GV and pSV3T3-20-GM were constructed by digesting pSV3T3-20-G to completion with *XbaI* and *HindIII* respectively, religating the digested DNA and transforming³ it into *Escherichia coli* HB101. pSV3T3-20-GEPM was constructed by inserting the *HindIII*-C fragment of SV40 DNA into the unique *HindIII* site of pSV3T3-20-GM. The DNA sequence of the virus-host junction was determined^{27,40} by sequencing from the *HindIII* and *XbaI* sites as indicated by the arrows.

Foci induced by pSV3T3-20-G appear about 10 days after those induced by the complete SV40 early region and are morphologically quite distinct, being flatter and less clearly delineated. Cells cloned from such foci are able to overgrow a monolayer of normal cells, have a more rounded morphology than the parental fibroblasts and multiply rapidly in medium containing 2% (v/v) fetal calf serum. This type of transformation has no precedent and we therefore examined the SV3T3-20-G DNA for unusual properties, first by determining the DNA sequence across the virus-host junction.

Fig. 2 Transformation by pSV3T3-20-G. Plasmid DNA (40 μg) was transfected into confluent monolayers of rat-1 cells grown on 50-mm dishes using a slight modification²³ of the calcium phosphate co-precipitation technique²⁴. Cells were maintained as monolayers in Dulbecco modified Eagle's medium supplemented with 5% (v/v) fetal calf serum and antibiotics. The dishes were fixed and stained²³ 30 days after transfection. Cells were transfected with vector (pAT153) DNA, pSV3T3-20-G and two other recombinant plasmids (pSV3T3-20-K and pSV3T3-20-L1) which contain tandem duplications in the viral early transcription unit and which transform as well as, if not better than, wild-type SV40 DNA²³.

We constructed subclones containing the virus-host junction, together with either the entire viral (pSV3T3-20-GV) or mouse chromosomal (pSV3T3-20-GM) segments, and determined the junction sequence as indicated in Fig. 1. The sequence obtained shows several interesting features (Fig. 3). An mRNA transcribed from the SV40 early promoter of SV3T3-20-G and containing the large T-antigen splice could be translated in the large T reading frame for 23 nucleotides beyond the virus-host junction, which occurs at SV40 nucleotide 3,713. Such a transcript would encode a truncated T antigen of calculated MW 45,000, the seven C-terminal amino acids of which are encoded by the flanking mouse DNA. Ten nucleotides beyond the translational stop codon is the sequence TATAAA which is one base removed from the canonical polyadenylation signal AATAAA^{25,26}. Transcripts of the size predicted if polyadenylation occurs at this site are found in SV3T3 C120 (ref. 27 and M.L. and P.W.J.R., unpublished data) and in cells transformed by pSV3T3-20-G (data not shown). In addition, cells transformed by pSV3T3-20-G contain the predicted truncated T antigen, which has an apparent MW of 48,000 (Fig. 4) and is also found in SV3T3 C120 (ref. 27). This protein may therefore be capable of inducing transformation.

An alternative explanation for our data was that the integration of the SV40 DNA had activated the adjacent DNA which contains a cellular transforming gene, a possibility strengthened by the sequence of the flanking mouse DNA (Fig. 3). Close to the virus-host junction there is a perfect consensus 'TATA' box, a feature of the 5' ends of eukaryotic RNA polymerase II transcription units²⁸. A sequence closely related to the consensus mRNA cap site²⁸ is located 34 nucleotides downstream of the first T of the 'TATA' box and this is followed, 42 nucleotides from what would be the initiating nucleotide, by an ATG triplet which marks the beginning of an open reading frame. It thus appears possible that the SV40 DNA has integrated next to a cellular gene. Neither we (D.M. and P.W.J.R., unpublished data) nor others^{29,30} have observed anything similar in other SV40-host DNA junctions.

We therefore attempted to transform cells with the viral and cellular segments in isolation. We also constructed an additional plasmid, pSV3T3-20-GEPM (Fig. 1), in which the segment of

T	Arg	Phe	Asn	Asp	Leu	Tyr	Pro	Gln	Ser	Thr

transfected DNA lacked both the termination codon for large T antigen and the polyadenylation site, so expression of a large T antigen-related protein could only occur if the integration event served to restore these control signals, a process which is certain to be extremely inefficient. In SV3T3-20-G the virus-host fusion required has already occurred.

When stained³⁷ for SV40 T antigen using the monoclonal antibody PAb419, which recognizes a determinant common to small and large T antigens³⁸, cells transformed by pSV3T3-20-G stain weakly in both nucleus and cytoplasm. The lack of nuclear retention suggests that the truncated T antigen may have a reduced ability to bind to DNA. It clearly does not bind to the cell-coded p53 protein (Fig. 4).

Colby and Shenk have recently shown³⁹ that SV40 genomes containing deletions which remove sequences coding for the C-terminal half of large T antigen, including the termination codon but not the polyadenylation signal, can immortalize rat embryo cells. Some of the cell lines thus generated have a fully transformed phenotype. The portion of the T antigen gene contained in their constructs is almost identical to that in SV3T3-20-G. However, their cell lines contain unstable T antigens whereas that encoded by SV3T3-20-G seems to be stable, a difference which may be due to the absence of the termination codon in their mutants. More surprising is the observation that their cell lines contain high levels of p53 whereas cells transformed by pSV3T3-20-G do not. These two sets of data clearly establish that the N-terminal half of large T antigen can mediate both immortalization and transformation. Our assay system is different from that used by Colby and Shenk and further studies are therefore required to explain the differences between the two sets of results.

The protein encoded by SV3T3-20-GV may transform through a hitherto unsuspected and novel property of large T antigen, perhaps by a mechanism quite distinct from that used by the intact protein. This idea is consistent with the fact that foci induced by pSV3T3-20-G are clearly distinguishable from those induced by intact SV40 DNA. The structure of SV3T3-20-G and our preliminary transcription data also raise the possibility that the integration of SV40 DNA may lead to the activation of adjacent cellular sequences.

We thank Wendy Colby and Tom Shenk for communicating unpublished data. D. M. holds a MRC research studentship and P. W. J. R. a Career Development Award from the CRC which also paid for this work.

onc gene amplification in promyelocytic leukaemia cell line HL-60 and primary leukaemic cells of the same patient

Riccardo Dalla Favera, Flossie Wong-Staal & Robert C. Gallo

Laboratory of Tumor Cell Biology, National Cancer Institute, National Institutes of Health, Bethesda, Maryland 20205, USA

Cellular *onc* genes are a group of evolutionarily conserved sequences which are homologous to the transforming genes (*v-onc*) of oncogenic retroviruses¹. Their function in normal cells is not yet known, but the sequence homology between viral and cellular *onc* genes is consistent with the idea that neoplastic transformation may, in some cases, be due to increased levels of cellular *onc* gene expression. The cellular homologue, *c-myc*, of the transforming gene of avian myelocytomatosis virus (MC29)^{1,2} is involved in the pathogenesis of chicken B-cell lymphomas induced by the non-acute leukemia virus (RAV-2)³⁻⁶, and in these tumours, *c-myc* expression is enhanced by the nearby integration of the RAV-2 terminal repeat region³⁻⁶. Transcripts from the *c-myc* gene are detectable in a variety of human cells^{7,8}, and increased levels of *myc* mRNA have been occasionally detected in some neoplastic tissues^{7,8}. The highest levels have been detected in the cell line HL-60 (ref. 8) derived from neoplastic cells from a patient with acute promyelocytic leukaemia (APL)⁹. We have now investigated whether any structural alteration at the genomic level could account for the increased expression of *c-myc* in HL-60 and report here that the *c-myc* gene is stably amplified in HL-60 DNA. Amplification was also detected in primary uncultured leukaemic cells from the same individual, suggesting that the *c-myc* amplification may have been involved in the leukaemic transformation in this case.

The genomic organization of human *c-myc* sequences has recently been studied in our laboratory¹⁰. Isolation and characterization of several recombinant phages from a human DNA library suggested the existence of at least one complete gene and several partially related sequences which may represent pseudogenes¹⁰. The complete *c-myc* gene spans ~4.5 kilobases (kb) of the human genome where two *v-myc* homologous exons are interrupted by one intron¹⁰. Three putative pseudogenes, each of which contains ~0.3 kb of *c-myc*-related sequences and lacks 3' and 5' regions of the gene, have been characterized¹⁰. Northern blotting hybridization experiments using a *v-myc* probe revealed a 2.7 kb mRNA transcript in a wide variety of human haematopoietic and nonhaematopoietic cells, including normal fibroblast and normal peripheral blood lymphocytes^{7,8}. In most of the cells, *myc* mRNA was present in 1-10 copies per cell⁸. However, at least a 10-fold increase in mRNA was observed in a few cases, including one sarcoma, two carcinomas and two haematopoietic cell lines⁸. The highest levels of *myc* RNA were present in the human promyelocytic leukaemia cell line HL-60 (ref. 8). This cell line has the capability to differentiate into mature nonproliferating granulocytes on induction with several chemical agents, including dimethyl sulfoxide (DMSO)¹¹ and retinoic acid¹². *myc* transcripts were virtually undetectable in terminally differentiated HL-60 (ref. 8). To investigate whether any structural alteration of the *c-myc* gene or adjacent regulatory regions could account for the increased *c-myc* expression in HL-60, we have now analysed the structure of *c-myc* sequences in these cells by Southern blot hybridization¹³. Our study included DNA from the HL-60 cell line,

Fig. 1 Amplification of *c-myc* sequences in HL-60 DNA. DNA was extracted as previously described²⁴ from: a, peripheral blood ALL cells; b, peripheral blood CLL cells; c, HL-60 passage 70; d, peripheral blood APL cells; e, normal human spleen; f, Molt 4 cell line; g, human breast carcinoma cell line; h, peripheral blood APL cells; i, peripheral blood AMML cells; j, peripheral blood APL cells; k, peripheral blood CML cells, partial digestion; l, uncultured HL-60 cells; m, normal human peripheral blood lymphocytes; and 20 μ g were digested with *SsrI* restriction endonuclease in standard conditions recommended by the supplier. Fragments were separated by electrophoresis on a 0.8% agarose gel. DNA was denatured, transferred to nitrocellulose as described by Southern¹³ and hybridization was performed using dextran sulphate²⁵. The probe was 2×10^6 c.p.m. of nick-translated pMC41-3RC DNA. pMC41-3RC is a recombinant pBR322 plasmid derived from λ LMC41, the recombinant Charon 4A phage containing the human *c-myc* gene¹⁰. For subcloning into the plasmid, a 1.4 kb *ClqI*-*EcoRI* fragment containing the *c-myc* 3' exon¹⁰ was isolated on preparative agarose gel and ligated into *ClqI*-*EcoRI*-cleaved pBR322 (ref. 26).

from primary leukaemic cells of the same individual, from normal human tissues (peripheral blood lymphocytes and spleen) and different neoplastic cells. The latter were obtained from peripheral blood of patients with acute myelogenous leukaemia (AML; 3 cases), chronic myelogenous leukaemia (CML; two cases), APL (three cases), acute lymphocytic leukaemia (ALL; one case), chronic myelogenous leukaemia (CML; one case), acute myelomonoblastic leukaemia (AMML; one case) and from cell lines representing myeloid (KG-1 and K562: refs 14, 15 respectively) and lymphoid (Molt 4)¹⁶ leukaemia (AML; three cases), chronic myelogenous leukaemia endonuclease and hybridized to a probe (pMC41-3RC) derived from the 3' exon of the human *c-myc* gene (see Fig. 1 legend for details). This probe hybridizes to a single 2.8 kb *SsrI* fragment in human DNA and does not hybridize to any of the putative pseudogenes because they are homologous only to the 5' exon of the *c-myc* gene¹⁰.

Representative results shown in Fig. 1 indicate the intensity of the 2.8 kb band was approximately identical in DNA from all samples except the HL-60 cell line and the patient's original uncultured cells, in which cases the intensity was markedly increased. Similar results were obtained with DNAs from different passages of the HL-60 cell line and in differentiated cells after induction with DMSO (data not shown). These data suggest that the *c-myc* gene copy number is increased in HL-60 cells. To investigate the extent of amplification of *c-myc* sequences in the HL-60 genome we hybridized *EcoRI* digests of DNA from primary and cultured HL-60 cells to a probe (pMCO) containing the entire *v-myc* gene¹⁰. This probe detects all *c-myc* related sequences in the human genome, including the putative pseudogenes¹⁰. Figure 2 shows that the intensity of a 12.8 kb band, which corresponds to the entire functional gene, is markedly increased in the two HL-60 samples, confirming the results shown in Fig. 1. In contrast, the intensity of the 5.8 kb band, which corresponds to one of the *c-myc* putative pseudogenes, is uniform in all the samples, suggesting that the functional gene, but not the other related sequences, is amplified. Moreover, this band serves as an internal control, proving that the difference in intensity of the 12.8 kb band is not due to experimental artefacts such as irregular DNA transfer or non-uniform hybridization across the nitrocellulose filter. In addition, a 4.6 kb fragment appears in the two HL-60 DNA samples but not in the other samples. The origin of this fragment is unknown. We suggest that it could represent either an

unidentified pseudogene which would be part of the amplification unit or a new fragment generated during the *c-myc* amplification event in HL-60 cells. Finally, experiments were performed to quantify the amplification of *c-myc* in HL-60. Thirty μ g of *SsrI*-digested HL-60 DNA were sequentially diluted (see Fig. 3) and the intensity of the hybridization band was compared with that obtained with 30 μ g of normal human lymphocyte DNA. Hybridization to a probe derived from another human *onc* gene, *c-sis*, which is a single copy gene¹⁷, was used as a control in the same experiment. Whereas the intensity of the *c-sis* band is comparable in normal spleen and undiluted HL-60 DNA, a 16- to 32-fold dilution is necessary to bring the *c-myc* band to the same levels as the control DNA. These data indicate that the *c-myc* gene is amplified 16- to 32-fold in HL-60. Similar estimates were obtained by direct densitometric screening of X-ray films from experiments shown in Fig. 1.

Our data thus indicate that the *c-myc* *onc* gene is amplified in the genome of HL-60 cell line, as well as in the original uncultured leukaemic leukocytes which were obtained from the peripheral blood of the patient before any chemotherapeutic treatment¹⁸. The levels of *c-myc* amplification do not seem to vary during prolonged cell culture or after induction to differentiation. This result cannot be simply explained by amplification of specific chromosome(s) in these cells because they are hypodiploid and no hyperdiploidy of individual chromosomes was observed¹⁸. However, different amplified genes have been reported to be located in double minutes or homogeneous staining regions of chromosomes (for review, see ref. 19). Since double minutes have been described in the HL-60 cell line¹⁸, we are currently investigating whether these structures could contain amplified *c-myc* sequences. The *c-myc*-containing amplification unit must be larger than the 12.8 kb *EcoRI* fragment which is conserved in HL-60 DNA. The amplified fragment could be considerably larger, however, as amplified units ranging from 500 to 1,350 kb have been reported¹⁹. The amplified fragment does not contain any of the putative pseudogenes, indirectly suggesting that these are not in the immediate proximity of the *c-myc* gene in the human genome.

Although *c-myc* amplification is confirmed in HL-60 cells, we do not yet know whether *c-myc* is amplified in the other non-leukaemic cells of the same individual because tissues other than the leukaemic cells are not available from the patient. In the absence of these critical data, at least three different hypotheses can be formulated.

Fig. 2 Hybridization of HL-60 and other human DNAs to *v-myc* probe (pMCO). Thirty μ g of DNA from: a, HL-60 passage 70; b, uncultured leukaemic HL-60 cells; c, normal human spleen; d, peripheral blood AML cells; e, Molt 4 cell line; f, peripheral blood normal human lymphocytes; were digested with *EcoRI* and hybridized to a *v-myc* probe (pMCO)¹⁰ as described in Fig. 1 legend.

Fig. 3 Estimate of *c-myc* copy number in HL-60 DNA. For this Southern blot dilution experiment, all the DNAs listed below were digested with *Sst*I and simultaneously hybridized to pMC41-3RC and to a human *c-sis* probe (pL335)^{17,27}. *c-myc* and *c-sis* hybridization bands in 30 µg of DNA from normal human lymphocytes (lane C) were used as standards and their intensity compared with that obtained with the same amount of DNA from uncultured HL-60 cells (lane 1) and serial dilutions of the latter with equal amounts of *Sst*I-digested salmon sperm DNA. The reciprocal of the dilution factor is shown above the lanes. Salmon sperm DNA was chosen as diluting DNA as *c-myc*- or *c-sis*-related sequences are not detectable in these conditions of hybridization, as shown in lane S (30 µg). The 2.8 kb *c-myc* band in lane C is intermediate in intensity between the bands in lanes 16 and 32. The 3.7 kb band closely matches the one in undiluted NL-60 DNA. Therefore, the *c-myc* copy number is between 16- and 32-fold higher in HL-60 compared with the normal standard. In contrast, the unamplified *c-sis* gene is present as a single copy in both genomes. The slight difference in migration of diluted samples is due to decreased salt concentration after the dilution procedure.

(1) *c-myc* amplification has occurred in the germ line. As individuals of the same species usually have the same number of copies per cell of a given gene, germ-line amplification in a single individual would be novel and of, as yet, unknown significance. Another example of germ-line amplification also involves a cellular *onc* gene, *c-ras*, which is amplified in different but closely related murine species²⁰. Although this case differs from *c-myc* amplification in HL-60 as it affects an entire species²⁰, taken together, these preliminary observations could point to a relatively high genetic mobility of cellular *onc* genes.

(2) *c-myc* amplification may be present in other non-malignant myeloid cells, perhaps representing a normal event during myeloid differentiation analogous to the developmental amplifications of chorion genes during oogenesis in *Drosophila*²¹ or actin genes during myogenesis in chickens²². In this case, the 'freezing' of HL-60 cells by the transformation event in a stage when *c-myc* is amplified and thus expressed at high levels could correlate with the unique ability of HL-60 to propagate as a cell line in the absence of growth-stimulating factor(s)¹¹.

(3) *c-myc* amplification only in the leukaemic clone may have important implications for the pathogenesis of leukaemia in this patient. It has been proposed that increased expression of cellular *onc* genes may cause neoplastic transformation. Thus, the finding of *onc* gene amplification correlating with increased levels of expression in HL-60 cells suggests an alternative mechanism to the 'downstream' promotion of *onc* genes by viral promoters^{3-6,28}. The *onc* gene amplification model cannot be generally applied, at least in the case of *c-myc* and haematopoietic neoplasias, because this gene is neither amplified nor expressed⁸ above basal levels in a small group of fresh leukaemic cells or cell lines tested in this study. In particular, it is not amplified in three cases of APL tested, although no data are available on its expression in these cells. Alternatively, HL-60 cells may belong to a separate subgroup of APLs as they do not display the karyotypic abnormality involving a reciprocal translocation between chromosomes 15 and 17 (ref. 18) commonly found in this type of leukaemia²³. These observations suggest that if *c-myc* amplification is involved in leukaemic transformation in HL-60, different mechanisms, including activation of different cellular *onc* genes, may lead to transforma-

tion even in similar neoplastic diseases. The validity of the *onc* gene amplification model can be tested in several different tumours expressing high levels of any of the known cellular *onc* genes.

We thank T. S. Papas for a gift of the MC29 clone from which the pMCO probe was derived, E. P. Gelmann for preparing the pMCO recombinant plasmid, J. D. Rowley for providing leukaemic cells from some of the APL cases and Anna Mazzuca for secretarial assistance. R.D.F. is a Special Fellow of the Leukemia Society of America.

Note added in proof: Using a chicken *c-myc* probe Collins and Groudine have independently achieved similar results on *c-myc* amplification in cultured HL-60 cells (S. Collins, personal communication).

Participation of myeloid leukaemic cells injected into embryos in haematopoietic differentiation in adult mice

Elisha Gootwine*, Cynthia G. Webb* & Leo Sachs†

Departments of *Hormone Research and †Genetics, Weizmann Institute of Science, Rehovot 76100, Israel

It is of interest to determine to what extent malignant cells are still subject to control mechanisms that govern the growth and differentiation of their normal counterparts¹⁻⁴. One approach has been the introduction of malignant cells into a normal embryo. Such studies have shown that mouse teratocarcinoma cells injected into blastocysts can participate in normal development to produce adult chimaeric animals with markers derived from teratocarcinoma cells^{1-3,5-7}. Other types of malignant cells may also be able to participate in normal morphogenesis, provided that they have the ability to differentiate and are introduced into the embryo at an appropriate stage of development. Here we have examined myeloid leukaemic cells and our results indicate that injection of these cells into embryos *in utero* at 10 days of gestation can produce apparently healthy adult mice whose granulocytes contain a marker derived from the leukaemic cells.

Table 1 Microinjection of myeloid leukaemic cells into the fetal placenta *in utero*

Survival of injected animals	Control	Experimental injected on:	
		Day 10	Day 11
Number of females operated on	13	26	58
Females dead post-operation	3	5	9
Females aborting	6	11	28
Females pregnant at term	4	10	21
Number of fetuses injected	141	268	469
Fetuses in females pregnant at term	33	94	156
Viable progeny	16	39	90
Animals dead after birth	2	7	35
Animals surviving	14	32	55

Fetuses were microinjected through the uterine wall into the fetal placenta¹². Each injection contained $\sim 5 \times 10^4$ cells and the cells were injected in the culture medium used for growing the leukaemic cells¹¹ without serum. Of 129 animals born, 70 were injected with leukaemic clone 7-M18 and 59 with leukaemic clone 1. Of 87 surviving animals, 45 were injected *in utero* with clone 7-M18 and 42 with clone 1. There was no statistically significant difference between groups receiving either of these clones and these data have therefore been pooled. Controls were injected with culture medium alone. Of the 84 females injected with leukaemic cells in these experiments, 75 were C3HeB and 9 were C57BL/6. The two apparently healthy adult mice with donor type enzyme (Table 2) were both obtained after injection of leukaemic cells into the fetal placenta of C3HeB mice.

We have used in these studies two clones of mouse myeloid leukaemic cells that grow in culture as myeloblasts to promyelocytes and which differ in their capacity to be induced to differentiate to mature macrophages and granulocytes by the normal macrophage and granulocyte differentiation-inducing protein MGI-2^{4,8-11}. One clone (7-M18) could be induced by MGI-2 to differentiate in culture to mature macrophages or granulocytes (mainly macrophages), whereas the other clone (1) could not be induced by MGI-2 to differentiate in culture to mature cells^{10,11}. To test for the incorporation of a marker from the leukaemic cells into the haematopoietic cell system, fetal mice were injected *in utero* with the myeloid leukaemic cells at 10 or 11 days of gestation. The leukaemic cells were from the strain SJL and the host animals injected were strains C3HeB or C57BL/6. Both clones of leukaemic cells contain the slow migrating glucose phosphate isomerase (GPI) isozyme GPI-1^a, whereas cells from C3H and C57BL/6 mice are homozygous for the fast migrating isozyme GPI-1^b. Leukaemic cells were microinjected into the placenta of each fetus according to the procedure described for injection of normal haematopoietic cells¹² and the numbers of viable progeny obtained are shown in Table 1.

In the first series of experiments, leukaemic cells were injected on day 10 of gestation (the day of plug was designated day 0) and 39 animals were born. One litter of four animals was cannibalized by the mother shortly after birth and another

Fig. 1 Glucose phosphate isomerase isozyme analysis by starch gel electrophoresis of extracts from peritoneal exudate cells. Granulocytes or macrophages were collected from the peritoneal cavity after injection of sodium caseinate. No leukaemic cells were observed. *a*, C3H control granulocytes; *b*, SJL control granulocytes; *c*, F1 (C3H×SJL) heterozygous control macrophages; *d*, mouse 30A, granulocytes at 4 weeks after birth (no donor-type enzyme); *e*, mouse 32A, granulocytes at 4 weeks after birth (no donor-type enzyme); *f*, mouse 14A, granulocytes at 3 months after birth (host and donor-type enzymes present); *g*, mouse 24A, granulocytes at 4 weeks after birth (host and donor-type enzymes present); *h*, F1 (C3H×SJL) heterozygous control granulocytes.

three animals died, were partially eaten and could not be examined. A total of 32 animals survived after weaning at 21–28 days (18 males and 14 females); these were screened for donor type enzyme beginning at or shortly after weaning, and then at about bimonthly intervals. Granulocytes were the first cell population examined. These cells were flushed from the peritoneal cavity after injection of sodium caseinate and analysed for GPI isozyme pattern by electrophoresis¹³.

Of the 32 adult animals injected with leukaemic cells *in vivo* at 10 days of gestation, two were found to have donor type enzyme in their granulocytes. Animal 14A was a female injected with cells of clone 7-M18 and animal 24A a male injected with cells of clone 1. In both these animals there was a major contribution of donor type (GPI-1^a) enzyme in the granulocyte samples collected at the age of 1 month (Fig. 1). Densitometric analysis of the electrophoretic pattern indicated that in these samples the donor type enzyme contributed at least 25% of the GPI activity. In both animals this contribution gradually decreased with age. We found 15–20% donor-derived GPI activity in the granulocytes at 3 months of age, 10% at 5 months, and only 5% at 7 months. This isozyme was no longer detected at 8.5 months in animal 14A and 10 months in animal 24A. A minor contribution of donor type isozyme was also detected in the leukocytes isolated from the peripheral blood up to 3 months of age in the case of animal 14A and 5 months in the case of animal 24A and this could be accounted for by the granulocytes in the peripheral blood. However, this isozyme was not detected in the peritoneal macrophages in these mice (Table 2). The leukaemic cells injected into the fetuses could be readily distinguished from normal peritoneal granulocytes (Fig. 2). At least 1,000 cells per sample were examined microscopically, and no leukaemic cells were seen in the peritoneal exudate or peripheral blood cells in these or any of the other adult mice. At autopsy, when the granulocytes no longer showed donor type isozyme, there was also no detectable amount of this enzyme in the spleen, thymus, bone marrow, kidney, liver or brain.

In a second series of experiments, leukaemic cells were injected at day 11 instead of at day 10 of gestation. In this series of injections 90 viable progeny were obtained, of which only 55 survived beyond weaning. None of these 55 mice showed detectable donor type GPI in their peritoneal granulocytes or macrophages. In these experiments 39% of the injected animals died before weaning. In some cases the carcasses had been partially eaten or post mortem changes were too marked to

Table 2 Donor type GPI isozyme in adult animals microinjected *in utero* with myeloid leukaemia

Animal no.	Clone injected	Age tested (months)	% Donor-type isozyme in:			
			Peritoneal cells		Peripheral blood	
			Granulocytes	Macrophages	Leukocytes	Erythrocytes
14A	Clone 7-M18	1	25	0	3	0
		3	20	0	3	0
		5	10	ND	0	0
		7	5	ND	0	0
		8.5	0	0	0	0
24A	Clone 1	1	25	0	3	0
		3	15	0	3	0
		5	10	ND	3	0
		7	5	ND	0	0
		10	0	0	0	0

Peritoneal granulocytes and macrophages were collected at 16 and 72 h, respectively, after intraperitoneal injection of 10% sodium caseinate solution. The peritoneal cell populations contained on average ~90% granulocytes and 80% macrophages. The other cells in the peritoneal samples used were lymphocytes and no leukaemic cells were observed. Peripheral blood samples were collected from the retro-orbital sinus and the erythrocytes and leukocytes separated. Leukaemic cells were also not observed in these samples. Cell pellets were suspended in water, lysed by three cycles of freezing and thawing, and the supernatants, obtained after centrifugation for 30 min at 28,000g, were electrophoresed on starch gels and stained as described elsewhere¹³. Per cent donor-type enzyme values represent estimates based on densitometric analyses of the electrophoretic pattern of GPI. ND, not determined.

Fig. 2 *a*, Peritoneal granulocyte population collected from healthy adult mice; *b*, myeloid leukaemic cells (clone 7-M18). Cells stained with May-Grunwald-Giemsa. $\times 630$.

allow enzymatic examination. Of the remaining 18 mice that died before weaning, 9 had tumours derived from the injected leukaemic cells, as determined by GPI analysis; the rest appeared to predominantly have severe bacterial pneumonia. The animals died with tumours by 15 ± 1 days after birth, that is, 3.5 weeks after injection of the leukaemic cells. The mean survival time of the tumour-bearing animals injected *in utero* was similar to that of neonatal syngeneic mice injected within 12 h of birth with an equivalent number (5×10^4) of leukaemic cells.

The present experiments indicate that malignant cells other than teratocarcinoma cells injected into embryos may participate in normal development. In two animals injected *in utero* with myeloid leukaemic cells on day 10 of gestation, at least 25% of the glucose phosphate isomerase in the peritoneal granulocytes was donor specific at 1 month after birth. Leukaemic cells were not seen in the cell populations analysed and these adult mice seemed healthy. These results indicate that the myeloid leukaemic cells participated in haematopoietic differentiation in apparently normal adult mice. The donor type enzyme decreased gradually over a period of 7 months and was no longer detectable at the age of 8–10 months. The selection of one cell type over another has also been reported in haematopoietic chimaeric animals obtained after injection of normal haematopoietic cells¹², and in allophenic mice produced from aggregated blastomeres^{14,15}. Cells with a donor-derived marker may have a selective disadvantage compared with the host cells, resulting in a gradual decrease in their contribution to the total cell population, perhaps due to the presence of a limited number of precursors.

Injection of leukaemic cells into 10-day-old fetuses resulted in two adult mice having cells with donor type isozyme whereas injection into 11-day-old fetuses did not and gave some animals with tumours. Further experiments with larger number of animals are required to determine the importance of a specific stage of embryonic development for obtaining adult animals with a donor type marker. We injected the embryos at the stage when there appears to be considerable migration of the normal progenitors of granulocytes and macrophages¹⁶. Other tumour cells may need to be injected into blastocysts¹⁷. This has given chimaeras with teratocarcinoma^{1-3,5-7} but not with melanoma cells¹⁸. Others may need to be injected at different stages of development into the placenta¹², or directly into the fetus¹⁹. When leukaemic cells are induced to differentiate *in vitro* by the normal differentiation-inducing protein MGI-2, it is the leukaemic cells and not segregants that differentiate to mature cells^{4,9}. It has also been shown that leukaemic cells may differentiate better *in vivo* than *in vitro*²⁰. The finding of a donor cell marker in animals injected as embryos with malignant cells suggests that the malignant cells may respond to the controls that regulate normal growth and differentiation in the embryo, or the cells with a donor cell marker may be segregants with a non-malignant phenotype derived from the malignant cells, as can occur with sarcomas⁸. The use of additional donor-specific markers including chromosome markers should make it possible to distinguish between these possibilities.

We thank Professor H. B. Stein for his assistance in histopathological examination and Professor H. R. Lindner for his

helpful comments. This work was supported in part by a grant to H. R. Lindner from the Ford Foundation and the Rockefeller Foundation, New York, and to C.G.W. from the Binational Science Foundation. C.G.W. is the incumbent of the Pauline Recanati Career Development Chair in Immunology.

Production of a monoclonal antibody specific for Hodgkin and Sternberg-Reed cells of Hodgkin's disease and a subset of normal lymphoid cells

Ulrich Schwab*, Harald Stein*, Johannes Gerdes*, Hilmar Lemke*, Hartmut Kirchner†, Michael Schaad† & Volker Diehl†

* Institute of Biochemistry and Institute of Pathology, Christian Albrecht University, D-2300 Kiel, FRG

† Department of Haematology and Oncology, Medical School of Hannover, D-3000 Hannover 61, FRG

The origins of the neoplastic cells in Hodgkin's lymphoma¹, the Hodgkin (H) and Sternberg-Reed (SR) cells, are still obscure, and these cells appear to carry no markers found on any population of normal cells^{2,3}. However the recent establishment of permanent Hodgkin cell lines^{3,4} has led to the search for tumour-specific antigens and/or for membrane markers on H and SR cells which may indicate the normal equivalent cells. Here, we describe the production of mouse monoclonal antibodies against the Hodgkin cell line L428. One hybridoma antibody, Ki-1, was found to be specific for H and SR cells of all Hodgkin's lymphomas tested and a minute, but distinct new cell population in normal tonsils and lymph nodes.

The existence of H and SR cell specific antigens was suggested by a conventional rabbit antiserum raised against the L428 cell line. After absorption with various normal human cells, the anti-L428 antiserum proved to be selectively reactive with L428 cells and H and SR cells⁵. To further investigate these apparent Hodgkin-specific tumour antigens we have started to produce hybridoma antibodies directed against H and SR cell antigens⁶.

BALB/c mice were immunized with L428 cells according to the schedule described by Stähli *et al.*⁷. Spleen cells were fused with the non-secreting myeloma line X63-Ag8.653 (ref. 8). In one fusion experiment we selected 57 pre-cloned 'resp.' highly enriched hybridomas that showed strong reactivity with L428 cells and no reactivity with a 10 times higher number of pooled normal tonsil cells. The resulting 57 monoclonal antibodies were tested by using the immunoperoxidase staining technique on frozen sections of biopsy tissue infiltrated with Hodgkin's

disease^{9,10}. One of the hybridoma antibodies reacted with H and SR cells, but not with other cells in the biopsy tissue. This clone was designated Ki-1. The constant expression of the Ki-1 antigen on H and SR cells was confirmed by immunostaining tissue from 14 cases of Hodgkin's disease of the four main histological types (Table 1). The H and SR cells of all cases stained distinctly (Fig. 1), but the intensity of the staining varied. There was no correlation between intensity of staining and histological type.

The specificity of the Ki-1 antibody for H and SR cells was further demonstrated, as the antibody did not stain cells of more than 50 cases of non-Hodgkin's lymphomas of various types, one case of osteomyelosclerosis, two cases of malignant histiocytosis and two cases of histiocytosis X. The Ki-1 antibody also did not react with cells of normal peripheral blood, skin, liver, kidney, lung or brain, or with macrophages of different types or stages of differentiation (Table 2).

Stainings with a highly sensitive three-layer immunoperoxidase labelling technique of a large series of normal or hyperplastic tonsils and lymph nodes, however, yielded unexpected results. A small population of cells located around and between cortical follicles and, to a lesser extent, at the inner rim of follicular mantles showed weak, but distinct staining for Ki-1 (Fig. 2). These cells were smaller than typical H and SR cells and had one nucleus; the nucleolus was prominent, like that of H and SR cells. Such cells could not be demonstrated with the conventional rabbit antiserum raised against L428 cells that reacted specifically with H and SR cells. There are two possible explanations for this phenomenon: (1) the conventional rabbit anti-L428 serum recognizes an antigen different from

Fig. 1 Hodgkin and Sternberg-Reed cells in tissue infiltrated by Hodgkin's disease reacting selectively with the monoclonal antibody Ki-1. Lyophilized 8 μ m sections of frozen tissue biopsies were fixed in acetone for 10 min and subsequently in chloroform for 10 min, both at room temperature. The fixed sections were then incubated with undiluted hybridoma supernatants or hybridoma ascitic fluids (dilutions ranged between 1:1,000 and 1:50,000) for 30 min. After a short wash in phosphate-buffered saline (PBS) the sections were treated with peroxidase-conjugated anti-mouse Ig (Dako) for 30 min, followed by a short wash. This reagent was reabsorbed with insolubilized human serum and diluted 1:10 in PBS to which normal human serum (final dilution of 1:5) was added to block cross-reactivity against human immunoglobulin. To increase sensitivity, stainings were performed at 37 °C or the sections were incubated with a third antibody layer composed of peroxidase-conjugated goat anti-rabbit IgG antibody (Medac) diluted 1:10 in PBS to which normal human serum (final dilution of 1:10) was added. After a brief wash, peroxidase was made visible by incubating the sections with diaminobenzidine (0.6 mg per ml) and hydrogen peroxide (0.01%) for 10 min at room temperature. The sections were then washed in PBS, counterstained with haemalum and mounted for microscopic examination. Negative controls were performed with the non-reactive monoclonal antibody W6/32HK²⁵ and positive controls with a set of monoclonal antibodies reactive with IgM, IgD (Bethesda), T-cells (OKT3, Ortho) HLA-DR (Becton Dickinson) and other cells or antigens.

Fig. 2 A cluster of Ki-1-positive cells in a hyperplastic (non-malignant) human tonsil. They are chiefly located between, around and sometimes within the B-cell follicles. In other areas of the tonsil, there are fewer Ki-1 positive cells. Inset: Ki-1-positive cell at high power view. Note the sharply defined prominent nucleolus within the pale nucleus and the labelled abundant cytoplasm.

that detected by monoclonal antibody Ki-1, or (2) both reagents detect the same antigen, which is strongly expressed on H and SR cells but only weakly on the normal Ki-1-positive cells. The second possibility is conceivable, because the multiple-step absorbed rabbit anti-L428 serum had to be used at rather high concentrations even for the detection of H and SR cells. Thus, the titre might have been too low to produce sufficient staining of normal cells expressing only low amounts of the antigen.

We also investigated normal human bone marrow as a possible source of various precursor cells of the peripheral lymphoid tissues and blood. Stainings with a three-layer immunoalkaline phosphatase technique revealed only very few scattered Ki-1-positive cells among the haematopoietic cells. From the non-reactivity of Ki-1 antibody in a case of osteomyelosclerosis (Table 2), which is a neoplastic proliferation of cells of the granulopoiesis, erythropoiesis and thrombopoiesis, we conclude that Ki-1-positive cells in the normal bone marrow do not belong to one of those three major myeloid cell lineages.

The detection of Ki-1 antigen on a small number of normal cells in tonsils, lymph nodes and bone marrow suggests that it may be a differentiation antigen and not a virus-induced or tumour-specific antigen. The diagnostic value of the Ki-1 monoclonal antibody is not reduced by the occurrence of Ki-1 antigen on normal cells, because these cells are easily distinguishable from H and SR cells by morphological criteria. The expression of Ki-1 antigen on H and SR cells of all cases of Hodgkin's disease studied and the absence of Ki-1 antigen in non-Hodgkin's lymphomas demonstrates that this antigen may be used as a reliable marker for Hodgkin's disease. The constant expression of Ki-1 antigen on H and SR cells in all histological types of Hodgkin's disease also supports the view that H and SR cells of all variants of Hodgkin's disease are homogeneous in origin and nature and not heterogeneous as assumed by some investigators¹¹⁻¹⁴.

Table 1 Reactivity of cells of Hodgkin's disease with the antibody Ki-1

Histological type	No. of cases	No. of cases showing H and SR cells reactive with:		
		SK203 (directed at HLA-DR)	W6/32HK (inactive control)	Ki-1
Lymphocyte predominance	2	1	0	2
Nodular sclerosis	5	3	0	5
Mixed cellularity	5	4	0	5
Lymphocyte depletion	2	1	0	2
Total	14	9	0	14

Table 2 Reactivity of normal and malignant cells of various tissues with the antibody Ki-1

	No. of samples	SK203 (directed at HLA-DR)	Cells reactive with:	
			W6/32HK (inactive control)	Ki-1
Lymph nodes and tonsils	10	B-cells, macrophages, interdigitating cells	None	Usually only few, but sometimes clusters of cells showing weak reaction around, between and at inner rim of follicular mantles
Blood	5	Monocytes, B-cells	None	None
Bone marrow	2	Various cells	None	Very few, scattered cells
Thymus	1	Most of the non-lymphoid framework cells	None	Very few cells in the medulla
Lung	2	Macrophages	None	None
Kidney	3	Endothelial cells, intertubular fibrocytes, proximal tubules (weak reaction)	None	None
Liver	2	Kupffer's cells	None	None
Brain	1	Not done	None	None
Skin	2	Langerhans' cells	None	None
Piringer's lymphadenitis	1	B-cells, macrophages, interdigitating cells	None	Interfollicular areas with relatively many labelled cells
B-type chronic lymphocytic leukaemia	10	Tumour cells of all cases	None	None
Follicular lymphoma	15	Tumour cells of all cases	None	None
Lymphoblastic lymphoma of Burkitt type	5	Tumour cells of all cases	None	None
B-type large-cell lymphoma	10	Tumour cells of 4 of 5 cases	None	None
T-type chronic lymphocytic leukaemia	1	None	None	None
Lymphoblastic lymphoma of thymocytic type	3	None	None	None
Various lymphomas of peripheral T-cell type	8	None	None	None
Osteomyeloid sclerosis (containing nearly all maturation forms of the granulocyte- and thrombopoiesis)	1	Not done	None	None

So far, the cells from which H and SR cells are derived have not been identified. The small subset of cells detected by the Ki-1 antibody in normal lymphoid tissue may possibly give rise to H and SR cells in appropriate conditions. This may be the case as Hodgkin's disease usually starts to develop in those areas in which most of the small Ki-1-reactive normal cells are found, namely, the parafollicular area¹⁵. The Ki-1-positive normal cells were investigated using double immunofluorescent labelling and three-layer immunoperoxidase labelling of serial sections of tonsils and a case of Piringer's lymphadenitis, containing clusters of Ki-1-positive cells. Only the latter method was sensitive enough to obtain clear-cut results. The comparison of the single stained serial sections showed that the normal cell population expressing Ki-1 antigen does not react with antibodies directed at B cells (anti-IgM, anti-IgD), T cells (OKT11, ref. 16), macrophages (OKM1, ref. 17, monocyte.1, ref. 18 and monocyte 2, G. Nunez, *et al.*, in preparation and lysozyme), dendritic reticulum cells (R4/23, ref. 19), interdigitating reticulum cells (T-ALL 2, ref. 20), or cells of the granulopoiesis (Tü5, Tü6, Tü9, ref. 21, 3C4, ref. 22), erythropoiesis (anti-glycophorin A, ref. 23) or thrombopoiesis (J-15, AN-51, ref. 24). Thus, these data indicate that the Ki-1-positive normal cells lack markers specific to, or characteristic of all known cell types of the haemato-lymphoid system. It may be that the Ki-1 antibody detects a new, so far unidentified cell population in normal lymphoid tissue.

We thank Dr A. McMichael for the monoclonal antibodies J-15 and AN-51, Dr P. A. W. Edwards for monoclonal antibody against glycophorin A, and Dr A. Ziegler for monoclonal antibody W6/32HK. The technical assistance of Heinke Asbahr, Ilse Horn, Angela Gelhaus and Kirsten Tiemann is acknowledged. HLA-restricted lymphoproliferative responses to MN blood group determinants

M. A. Blajchman*, N. Heddle†, N. Naipul† & D. P. Singal†

* The Canadian Red Cross Blood Transfusion Service and Departments of Pathology and Medicine, McMaster University, Hamilton, Ontario, Canada L8N 3Z5

† Department of Pathology, McMaster University, Hamilton, Ontario, Canada L8N 3Z5

It is well established that strong proliferative responses in mixed lymphocyte culture (MLC)¹ are controlled by gene products of the *HLA-D* locus, but stimulation between *HLA-D* identical individuals does occur and may partly be due to differences at the *HLA-A*, or *HLA-B* loci. However, many unrelated individuals who type identically for *HLA-A*, *-B*, *-C*, and *-D/DR* determinants have also been shown to be mutually stimulatory. The development of the primed lymphocyte test (PLT) provided a powerful tool in the identification of these non-*HLA* loci²⁻⁹. Using this test, we show here that significant *HLA*-restricted proliferative responses occurred in association with M or N blood group antigens.

Lymphocytes, separated from freshly drawn blood, were primed to stimulating cells from allogeneic donors in long-term MLC as described previously⁹. Lymphocytes were typed for HLA-A, -B, and -C antigens by the microdroplet lymphocytotoxicity test with a battery of highly selected typing antisera¹⁰. HLA-DR typing was performed on a B-cell enriched lymphocyte population¹⁰. HLA specificities were defined on the basis of reactivity with sera from the VIIth and VIIIth International Histocompatibility Workshops.

To investigate the role of the M and N determinants in PLT, lymphocytes from M-negative or N-negative donors were primed in long-term cultures against cells from donors mismatched for the corresponding M or N antigen. These responder-stimulator combinations were also mismatched for one or two HLA-DR antigens. Primed lymphocytes were then tested for proliferative responses against stimulating cells from third-party allogeneic donors. Data from one experiment demonstrating the role of the M determinant in PLT are given in Table 1. Lymphocytes from donor A (HLA-A2, A26; Bw16, Bw44; DRw8; Nss) were primed against cells from donor B (HLA-A1, Aw24; B8, Bw58; Cw6; DR1; MNs) in long-term MLC. Primed lymphocytes were tested for proliferative responses against stimulating cells from 10 allogeneic donors. Primed lymphocytes responded to three donors (C, D, E) who are positive for the sensitizing DR1 specificity. Primed lymphocytes also responded to three M-positive, HLA-A2-positive, HLA-DR1-negative donors (F, G, H). On the other hand, primed lymphocytes did not respond to two M-positive A2-negative, DR1-negative donors (I, J) and to two M-negative, DR1-negative donors (K, L). Similar data were observed in two other PLT experiments; (1) HLA-A3, A29; B8, Bw45; Cw6; Ns anti-A2, A28; Bw39, Bw50; DR2, DRw6; MS, and (2) HLA-A1, B7, B8; DR3, DR5; Ns anti-A2, A28; Bw39, Bw50; DR2; MS. The data from these three experiments are summarized in Fig. 1a. Primed cells responded to cells from donors who are positive for the sensitizing DR specificity. These primed lymphocytes also responded to lymphocytes from M-positive, sensitizing DR-negative individuals who shared HLA-A antigen(s) with the responder cells. However, primed lymphocytes did not respond to lymphocytes from M-positive, specific-DR-negative donors who did not share HLA-A determinant(s) with the responder cells. Primed lymphocytes did not respond to stimulating cells from M-negative, specific-DR-negative donors (data not shown).

Data from an experiment demonstrating the role of the N determinant in PLT are given in Table 2. Lymphocytes from a donor A (HLA-A2, A28; Bw39, Bw50, DR2, DRw6; MS) were primed against cells from donor B (HLA-A1, B7, B8; DR3; DR5; Ns). Primed lymphocytes were tested for proliferative responses against stimulating cells from 12 allogeneic donors. Primed lymphocytes responded to four donors (C, D, E, F) who are positive for the sensitizing DR3 or DR5

Fig. 1 Responses of primed lymphocytes to allogeneic lymphocytes in the primed lymphocyte test. *a* Shows the responses of primed lymphocytes to the sensitizing HLA-DR and M determinants (data pooled from three separate experiments); *b* shows the responses of primed lymphocytes to the sensitizing HLA-DR and N determinants (data pooled from three separate experiments). A PLT response to allogeneic donor cells was considered positive when the per cent relative response (% RR) was more than the lower limit of the mean ± 2 s.d. (95% confidence limits) of the PLT responses to the DR-specific allogeneic donors. Cut-off point for the anti-M PLT response is 61%; for anti-N 67%.

specificity. Primed lymphocytes also responded to three N-positive, HLA-A2-positive, HLA-DR3, 5-negative donors (G, H, I), but did not respond to three N-positive, A2-negative, DR3, 5-negative donors (J, K, L) or to two N-negative, DR3, 5-negative donors (M, N). No response to the s determinant was observed in this experiment. Similar data were observed in two other PLT experiments; (1) HLA-A2, A28; Bw39, Bw50; DR2, DRw6; MS anti-A3, A29; B8, Bw45; Cw6; DR3; Ns, and (2) HLA-A1, A3; Bw35, Bw52; Cw4; DR1; Ms anti-A2, A28; B14, Bw60; CW3; DR7; MNs (Fig. 1b).

Highly significant associations were found between PLT and

Table 1 Responses of primed lymphocytes to M determinant in PLT

Stimulating cell	HLA type -A, -B, -C	-DR	MNSs	% Relative response	PLT determinant
B	A1, Aw24; B8, Bw58; Cw6	1	MNs	100	+
C	Aw24, Aw33; B14, Bw63	1	MSs	145	+

N	A1, A3, Bw35, Bw52; Cw4	2	Ms	50	-

Lymphocytes from donor A (HLA-A2, A28; Bw39, Bw50; DR2, DRw6; MS) were primed against cells from donor B in MLC. Primed lymphocytes were used at a concentration of 25×10^3 cells per well.

HLA-DR determinants, and between PLT and HLA-restricted M or N determinants (Table 3). No differences were observed in the responses of responder lymphocytes to stimulator cells from homozygous or heterozygous M or N individuals. In our panel of normal healthy subjects, we have only one HLA-D/DR-identical, M- or N-mismatched pair. Primed lymphocytes (HLA-A1; B7, B8; DR3, DR5, Ns anti-A1, A3; B8, Bw35; DR3, DR5; MNS) responded to four M-positive donors who shared an HLA-A antigen with the responder lymphocytes. Primed lymphocytes did not respond to M-positive stimulators who did not share an HLA-A antigen.

To investigate the role of the S and s genes in PLT, lymphocytes were primed in responder-stimulator combinations mismatched for the S (or s) and for one or two HLA-DR antigens. Primed lymphocytes were tested for proliferative responses against stimulating cells from third-party allogeneic donors. Lymphocytes from third-party donors, who are positive for the sensitizing DR antigen, elicited strong proliferative response in PLT. However, primed lymphocytes did not respond to stimulating cells from donors who are positive for the specific S or s determinant but negative for the sensitizing DR specificity. These third-party donors included individuals who shared HLA-A determinant(s) with the responder PLT

cells. This was observed in six experiments using different responder-stimulator combinations. Thus, no effects of S or s incompatibility were observed in PLT.

The above findings demonstrate that lymphocytes from individuals mismatched for M and N determinants can cause significant HLA-restricted proliferative responses in PLT. It appears that lymphoproliferative responses in the PLT to stimulating lymphocytes from M and N mismatched individuals require the simultaneous expression of the same HLA-A antigen(s) on both stimulator and the primed responder lymphocytes. On the other hand, no effects of S and s incompatibilities were observed in the PLT.

MNSs determinants appear to be associated with two human erythrocyte membrane sialoglycoproteins¹¹⁻¹³. The M and N determinants are associated with glycophorin A, while the S and s determinants are associated with glycophorin B¹⁴. Similar sialoglycoproteins have been demonstrated in the membranes of other cells such as platelets, granulocytes and lymphocytes^{14,15}. Whether these glycoproteins are associated with the M and N antigens in these cells is unclear.

Blood group incompatibility has been shown to play a part in organ transplantation in man. Graft versus host disease in patients receiving bone marrow transplants from HLA-identical siblings has recently been correlated with MNSs incompatibility¹⁶. The present data suggest that MN determinants, or closely related genes, are expressed on lymphocytes and can cause HLA-restricted proliferative responses in PLT which may be an important consideration in organ transplantation.

This work was supported by the MRC of Canada. We thank Dr W. Rawls of McMaster University and Dr M. Schanfield of the American Red Cross for helpful suggestions during the preparation of this manuscript.

Table 3 Association between HLA-A-restricted M or N determinants and HLA-DR in PLT

	Association*				χ^2	r	P
	+/+	+/-	-/+	-/-			
PLT/M(HLA-A restricted)	14	8	0	23	18.38	0.69	$<10^{-4}$
PLT/HLA-DR	20	22	0	23	13.66	0.49	$<10^{-3}$
PLT/N(HLA-A restricted)	13	7	2	19	11.30	0.58	$<10^{-3}$
PLT/HLA-DR	19	20	0	21	12.81	0.50	$<10^{-3}$

A PLT response was considered positive or negative using the criteria given in Fig. 1. The data were analysed using 2×2 comparisons of the determinants recognized by PLT and HLA-DR. For PLT/M or N(HLA-A restricted) comparisons, allogeneic donors positive for the sensitizing HLA-DR antigens were excluded from the analysis.

* Association terminology (for example, for PLT/M(HLA-A-restricted): +/+ indicates a positive PLT test associated with the presence of the M antigen and HLA-A restriction; +/- indicates a positive PLT test associated with the absence of the M antigen and HLA-A restriction; -/+ indicates a negative PLT test associated with the presence of the M antigen and HLA-A restriction; -/- indicates a negative PLT test associated with the absence of the M antigen and HLA-A restriction.

Monoclonal antibody defines a macrophage intracellular Ca^{2+} -binding protein which is phosphorylated by phagocytosis

David J. T. Vaux & Siamon Gordon

Sir William Dunn School of Pathology, University of Oxford, South Parks Road, Oxford OX1 3RE, UK

The macrophage is a highly phagocytic cell which has been widely used in attempts to dissect the mechanisms of endocytosis¹. In immune phagocytosis specific interactions occur between ligands on the presenting particle and Fc or C3b specific receptors expressed on the plasma membrane^{2,3}, but macrophages also avidly ingest particles such as polystyrene latex by an immunologically nonspecific mechanism. This process is guided by sequential ligand-receptor interactions^{4,5}. Biochemical studies indicate that actin, myosin and several regulatory components distinct from the troponin system of skeletal muscle, take part in phagocytosis by macrophages and polymorphonuclear leukocytes (PMN)⁶ and indirect immunofluorescence confirms the presence of these components at sites of phagocytic activity⁷. However, comparatively little is known about coupling between receptor binding and assembly of the contractile system, although electrical changes⁸ and the flux of divalent cations⁹ have been implicated. Here we report a monoclonal antibody that detects an intracellular protein from macrophages which binds Ca^{2+} in non-phagocytosing cells, and becomes phosphorylated as a result of phagocytosis. It might therefore take part in signal transduction during this process.

In an attempt to study antigenic components of the cytoplasmic face of the mouse macrophage phagolysosome membrane, rats were hyperimmunized with latex-containing phagolysosomes (LP) prepared by flotation in a discontinuous sucrose gradient¹⁰. Antibodies against LP were detected by trace indirect radioimmunoassay (RIA) and rats with high serum titres, $>1/1000$, used as spleen donors in myeloma fusions¹¹. Hybridoma supernatants containing antibodies for antigens on the cytoplasmic face of the phagolysosome membrane were screened on LP or on cells permeabilized by methanol fixation and positive cultures were cloned twice in soft agar. The present report studies PL4, one monoclonal antibody produced in this way.

The binding properties of PL4 were examined on intact or methanol-fixed thioglycollate-elicited mouse peritoneal macrophages (TPM), on LP isolated from such macrophages, and on mouse L-cell fibroblasts, which lack specific phagocytic pathways, but are able to ingest latex. The antigen it bound could be detected by RIA on LP (Fig. 1a), and in methanol-fixed, but not live TPM, even in the absence of a phagocytic stimulus (not shown). It was also detectable by RIA (Fig. 1b) and by FACS analysis (Fig. 1c) of permeabilized, but not intact (Fig. 1d) fibroblasts. Another monoclonal antibody, F4/80, which detects an external plasma membrane component of the macrophage¹², did not bind to isolated LP. Indirect immunofluorescence with fixed cells showed a granular cytoplasmic distribution, not confined to phagocytosing cells or the vicinity of phagolysosomes and the antibody recognizes a similar antigen in human and monkey, but not rat cells. We concluded that the antigen detected by PL4 is restricted to the inside of the cell and is present in macrophages as well as other cells, including cells which have not received a phagocytic stimulus.

If the inorganic phosphate pool within mouse macrophages is equilibrated with ^{32}P -labelled P_i, then a number of proteins associated with isolated LP become phosphorylated. PL4 specifically precipitates a labelled protein from lysates prepared from TPM after phagocytosis of latex microspheres (Fig. 2a,

arrow). This protein has a molecular weight of $\sim 19,000$ as estimated by SDS-polyacrylamide gel electrophoresis and was not detected as a phosphorylated molecule in control preparations without specific antibody or in the absence of a phagocytic stimulus (Fig. 2b-d).

If protein blotting techniques are used to produce nitrocellulose replicas of SDS-polyacrylamide gels then it is possible

Fig. 1 PL4 detects an intracellular antigen in macrophages and fibroblasts. PL4 cells were grown in Iscove's modified minimal essential medium (MEM) supplemented with 5% fetal bovine serum (FBS), heat inactivated for 30 min at 56 °C, and antibiotics (I+5). The antibody, a rat IgG2a, was precipitated with $(\text{NH}_4)_2\text{SO}_4$, washed, dissolved in phosphate-buffered saline, pH 7.4 (PBS) and dialysed against PBS + 10 mM NaN_3 . a, LP were prepared from homogenates of TPM fed 1.1- μm latex microspheres (LB11, Sigma) 15 h previously. RIA was performed²⁰ by incubating LP with serial dilutions of PL4 in PBS + 0.1% (w/v) BSA + 10 mM NaN_3 (PBA) for 1 h at 4 °C. PL were washed twice in PBA, pelleted for 3 min and incubated for 1 h at 4 °C with 3×10^5 c.p.m., ^{125}I -F(ab')₂ fragments of MRC OX12, a monoclonal mouse antibody against the rat heavy chain b allotype¹¹ donated by Dr S. Hunt. Samples were washed three times in PBA and LP counted in clean tubes in a Packard γ -counter. Results are given as mean counts bound ($n=2$, range $<10\%$ of mean). b, Mouse L929 cells²¹ were fixed in methanol at -20 °C for 6 min or used unfixed after a wash in PBA. Binding of PL4 was done as in a. Samples were resuspended in Isoton and the number determined in a Coulter counter. Results show mean counts bound per 10^5 cells ($n=2$, range $<10\%$ of mean). c, d, Live and methanol-fixed L929 cells were incubated with PL4 and then with tetramethylrhodamine conjugated OX12, 25 μg per ml. After washing, cells were examined using a fluorescence activated cell sorter (Becton Dickinson). The profiles display relative number against rhodamine fluorescence. Cell fragments and large aggregates were excluded electronically.

Fig. 2 PL4 precipitates a phosphorylated protein after phagocytosis. TPM were incubated for 1 day at 5×10^6 cells per 100-mm tissue culture dish (Corning 25020) in 5 ml of I+5 (see Fig. 1 legend). Adherent cells were washed twice in saline and 3 ml of MEM with 5% heat-inactivated FBS which was phosphate free, and 1 mCi per dish of $^{32}\text{P}_i$ (Amersham International). Dishes were incubated for 5 h to ensure equilibration of the phosphate pool (trichloroacetic acid-precipitable counts plateau by 90 min), the $^{32}\text{P}_i$ -containing medium was then aspirated and cells were washed with saline. Dishes were treated with 5 ml prewarmed I+5 with or without 1% latex and incubated at 37°C for 15 min. Cells were washed three times with ice-cold PBS with 10 mM NaN_3 and collected with a rubber policeman in 5 ml of ice cold collection buffer (PBS with 1% (v/v) aprotinin, 1 mM phenylmethylsulphonyl fluoride (PMSF), 2 mM EDTA and 10 mM NaN_3). Cells were centrifuged at 1,000 r.p.m. for 5 min and the pellet dissolved in 1 ml lysis buffer (PBS with 0.5% (v/v) NP40, 0.1% (w/v) SDS, 1% (v/v) aprotinin, 1 mM PMSF and 10 mM NaN_3) on ice, for 15 min. The lysate was clarified by centrifugation for 15 min and distributed to microfuge tubes for immunoprecipitation. 400 μl of lysate was incubated at 4°C for 1 h with 50 μl PL4 and then 25 μl of hyperimmune rabbit anti-rat IgG serum, heat inactivated at 56°C for 30 min and clarified by ultracentrifugation before use. The precipitate was collected by centrifuging for 10 min, washed three times in lysis buffer, and resuspended by sonication in 25 μl of 8 M urea, 5% (w/v) SDS in 25 mM Tris-HCl, pH 7.0. SDS-containing sample buffer (25 μl) was added, and the samples were boiled and analysed on 10% acrylamide SDS-polyacrylamide gels²². Gels were processed for fluorography²³, dried by vacuum and autoradiographed with Kodak X-Omat paper at -70°C for 18 days. Immunoprecipitates: a, PL4, after phagocytosis. b, PBA, after phagocytosis. c, PL4, no phagocytosis. d, PBA, no phagocytosis. ^{14}C -methylated protein markers (Radiochemical International) were run at the same time.

to detect proteins which bind $^{45}\text{Ca}^{2+}$. Figure 3 shows the major Ca^{2+} -binding species in a lysate prepared from TPM which have not received a phagocytic stimulus. When PL4 is used to immunoprecipitate unlabelled macrophage lysates insufficient protein is recovered to stain with Coomassie blue. However, after blotting and incubation with $^{45}\text{Ca}^{2+}$ it is clear that the antigen recognized by PL4 is a Ca^{2+} -binding protein (Fig. 3d) as well as a target for phosphorylation (Fig. 2a). Similar preparations of other monoclonal antibodies or heterogeneous antisera against LP do not precipitate this molecule. This novel method for detecting Ca^{2+} -binding proteins will reveal only those proteins with an affinity for Ca^{2+} below that of EDTA (otherwise EDTA will not release the unlabelled Ca^{2+} before replacement with $^{45}\text{Ca}^{2+}$) and has the disadvantage common to all nitrocellulose blotting techniques of reduced transfer efficiency with increasing molecular weight. However, the method can detect Ca^{2+} -binding proteins with molecular weight (MW) $>100,000$ (Fig. 3a).

Calcium-binding proteins of similar size have been isolated from various sources including calmodulin¹³, which is not phosphorylated, and myosin light chain¹⁴ which can be phosphorylated in certain conditions. We have found with the aid of sensitive radioimmunoassays that PL4 does not bind to highly purified vertebrate calmodulin¹⁵ or myosin light chains from bovine thymus or chicken gizzard¹⁶. As this antigen is neither species nor tissue specific we suspect that it is a different protein,

but further studies with affinity-purified material are needed to establish its identity.

The continuation of phagocytosis in the absence of extracellular calcium¹⁷ and the lack of muscle-like regulatory components of actomyosin have been used to argue against a role for Ca^{2+} in coupling ligand-receptor binding with actomyosin contraction in the macrophage. However, more recently it has

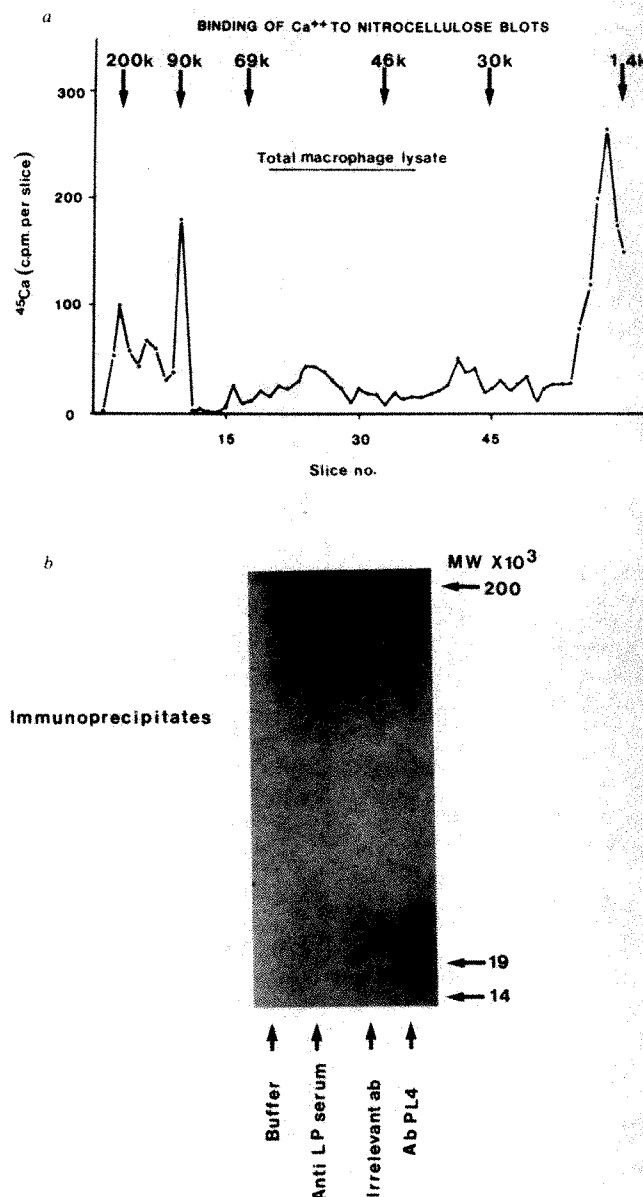

Fig. 3 The protein immunoprecipitated by PL4 binds Ca^{2+} . Unlabelled TPM were prepared without a phagocytic stimulus, as in Fig. 2. Total lysates and PL4 immunoprecipitates were processed and electrophoresed and the gel blotted on nitrocellulose filters by diffusion in transfer buffer (50 mM NaCl, 2 mM NaEDTA, 0.1 mM dithiothreitol in 10 mM Tris-HCl, pH 7.0) for 48 h²⁴. The filters were washed overnight at room temperature in PBS containing 10 mM NaEDTA, made in deionized water, and in three changes of deionized water (1 h each). Filters were incubated with $1 \mu\text{Ci cm}^{-2}$ $^{45}\text{CaCl}_2$ (Amersham International) in deionized water for 3 h at room temperature. Excess $^{45}\text{Ca}^{2+}$ was removed by washing in PBS. The filters were air dried and either autoradiographed with an intensifier screen (Fuji) using Kodak NST-1 film at 4°C for 15 days, or cut into 1-mm strips and counted in a Packard scintillation spectrometer. a, $^{45}\text{Ca}^{2+}$ -binding proteins of the macrophage lysate. Although it is possible to blot ^{14}C -methylated molecular weight markers, in this experiment the nitrocellulose blot was calibrated from markers run on an adjacent unblotted section of the parent gel. b, $^{45}\text{Ca}^{2+}$ -binding proteins after immunoprecipitation with PL4 or controls.

become clear that the macrophage does possess a molecule (gelsolin, MW ~93,000) which confers Ca^{2+} dependence on the contractile system⁶, and that this component is present at the site of phagocytosis (H. L. Yin, personal communication). It is therefore possible that the macrophage contractile machinery is ultimately under Ca^{2+} control, as in skeletal muscle¹⁸. If this is the case, then the lack of requirement for extracellular Ca^{2+} suggests that the local increased Ca^{2+} is due to some event other than an inward Ca^{2+} flux across the plasma membrane. The Ca^{2+} may be released into the cytosol from some intracellular site of sequestration, triggered by ligand-receptor binding at the cell surface. The component of the macrophage described here is a good candidate to mediate such a calcium signal and experiments are now under way to examine the kinetics of

phosphorylation and its effect on the Ca^{2+} -binding affinity of the molecule.

The antigen detected by PL4 is present in cells before phagocytosis and binds Ca^{2+} in this form, although incorporation of ^{32}P occurs only after a phagocytic stimulus. Nonphysiological stimuli which perturb the membrane such as phorbol myristate acetate¹⁹ also have this effect on the antigen. Further studies are needed to define the association between this antigen and the phagolysosomal membrane and its relation to phosphorylation by phagocytosis.

We thank Ms Maxine Bampton for technical help and Drs D. M. Watterson and J. Kendrick-Jones for purified calmodulin and myosin light chains. This work was supported by a research studentship and a grant from the MRC.

Dopaminergic supersensitivity induced by denervation and chronic receptor blockade is additive

D. A. Staunton, P. J. Magistretti, G. F. Koob, W. J. Shoemaker & F. E. Bloom

Arthur V. Davis Center for Behavioral Neurobiology, The Salk Institute, PO Box 85800, San Diego, California 92138, USA

A persistent, severe reduction of synaptic transmission has been shown to enhance the responsiveness of postsynaptic tissue to the deficient neurotransmitter—a phenomenon called postjunctional supersensitivity^{1–4}. Regardless of whether supersensitivity is induced by removal of presynaptic nerve terminals (denervation) or by chronic postsynaptic receptor blockade, qualitatively similar adaptations in peripheral autonomic targets are usually produced, suggesting that the two types of manipulation are interchangeable and that the postsynaptic molecular alterations they produce are identical². Following bilateral destruction of dopamine-containing afferents to the nucleus accumbens in the rat, there is a pronounced behavioural hyperresponsiveness to direct dopamine agonists^{5–7}. A remarkably similar situation develops after chronic administration of antipsychotic drugs^{8–10}, such as haloperidol, which are known to be potent antagonists at putative dopamine receptors^{11–13}. We report here that a combination of these two procedures unexpectedly leads to far greater dopaminergic supersensitivity than is observed with either treatment alone. In subjects with the combined treatments, the dopamine agonist apomorphine was more effective in tests of locomotor activation, and additive elevation of the B_{max} for ^3H -spiperone binding in the nucleus accumbens was observed. These results suggest that denervation and chronic exposure to receptor antagonists can lead to independent processes of postjunctional supersensitivity.

Male Sprague-Dawley rats (Charles River Laboratories; mean weight 305 g) were used. To study denervation supersensitivity, 8 μg of 6-hydroxydopamine were injected into the nucleus accumbens on each side as previously described¹⁴. Sham-treated control subjects were prepared with bilateral

injections of the ascorbate/Ringer's 6-hydroxydopamine vehicle. On the third post-surgical day, the animals were screened for dopaminergic behavioural responsiveness to apomorphine (0.1 mg per kg = 329 nmol free base per kg; method as in Fig. 1 legend). The cumulative counts were used to rank 6-hydroxydopamine- and sham-injected subjects into two equally responsive groups of the same size.

On the day following this screening, chronic drug treatment was initiated. Haloperidol (McNeil Injectable), 2.2 μmol per kg per day, was administered subcutaneously (s.c.) to one-half of the 6-hydroxydopamine-treated and one-half of the sham-treated animals for 14 (expt 2) or 15 (expt 1) days. The control animals were injected with haloperidol vehicle¹⁵ (see Fig. 1 legend for details). None of the treatments resulted in any overt toxicity.

Seventeen days after the lesions, the rats were tested for locomotor activation by various doses of apomorphine-HCl (32.9–329 nmol per kg, s.c.). On the day following the final behavioural assessment, the animals were decapitated and catecholamine levels in the nucleus accumbens were determined (see Fig. 2 legend).

A second series of animals (expt 2) were treated for analysis of nucleus accumbens neuroleptic-binding sites. The animals were evaluated for apomorphine-induced locomotor activity (0.1 mg per kg, s.c.) as detailed above on the second day of withdrawal from chronic drug administration. On the following day, the subjects were decapitated and ^3H -spiperone-binding sites in the nucleus accumbens were measured¹⁶.

Figure 1 shows the results of behavioural testing with apomorphine-HCl at one dose (165 nmol per kg). In both sham-lesioned animals chronically treated with haloperidol and animals receiving 6-hydroxydopamine injections and vehicle, apomorphine potentiated locomotor activity ($P < 0.01$ and $P < 0.001$ respectively). When treatment with 6-hydroxydopamine and chronic haloperidol injections were combined, the response to apomorphine was considerably greater than with either treatment alone. Spontaneous locomotor activity before apomorphine injection was not significantly different between groups. The same pattern of response was observed at all doses of apomorphine (Fig. 2). There were no significant effects of the saline/ascorbate vehicle.

Additional information was obtained by determining the ED_{50} values, defined as the dose of apomorphine which led to

Fig. 1 Locomotor activity following interscapular subcutaneous injection (at $t=0$ min) of 165 nmol per kg apomorphine-HCl. Before injection, the animals were allowed a 70–80 min habituation period in the testing cages, during which time no effects of the various chronic pretreatments were observed. Activity was evaluated in cages containing twin photocell beams as previously described¹⁵. The values are the mean photocell counts recorded during each preceding 10 min interval for the groups represented as follows: \circ , bilateral sham nucleus accumbens injections +15 days of haloperidol vehicle ($n=7$); \bullet , sham nucleus accumbens lesion +15 days of 1 mg per kg haloperidol s.c. ($n=8$); \blacktriangle , bilateral 6-hydroxydopamine (6-OHDA; 8 μ g each side) nucleus accumbens injections +15 days of haloperidol vehicle ($n=6$); \bullet , 6-hydroxydopamine nucleus accumbens lesions +15 days of haloperidol ($n=8$). Statistical analysis was accomplished with two-factor analysis of variance, which allowed the testing for main effects of chronic haloperidol and 6-hydroxydopamine treatment as well as for their interaction, with significance assumed in each case when $P < 0.05$.

a doubling of the cumulative activity scores in one-half of the subjects in each group compared with the control group. In animals receiving prolonged haloperidol treatment alone, ED_{50} was achieved in the range 82–165 nmol apomorphine per kg, while that for subjects receiving only 6-hydroxydopamine was 33–82 nmol per kg of apomorphine. In the case of the combined treatment, the apparent ED_{50} was observed with 33 nmol apomorphine per kg. The rats receiving the combined treatment were approximately twofold more sensitive to the locomotor activating effect of apomorphine than those with the lesion alone and approximately fivefold more sensitive than those receiving chronic haloperidol alone. Moreover, our data (Fig. 2) clearly demonstrate that the magnitude of locomotor activation induced by 165 and 329 nmol per kg of apomorphine in subjects with the combined treatment is greater than the sum of the apomorphine-induced activation seen with either treatment alone. Thus, the potency and efficacy of apomorphine were both enhanced in animals with the combined treatment compared with those with either treatment alone.

Figure 3 shows a part of a Scatchard¹⁶ analysis of 3H -spiperone binding to membranes prepared from the nucleus accumbens of the similarly pretreated groups of expt 2. Statistical analysis revealed two significant effects—an elevation of B_{max} values produced by treatment with the neurotoxin ($P < 0.001$) and a separate elevation produced by chronic administration of haloperidol ($P < 0.001$). There was no significant interaction of 6-hydroxydopamine and the chronic neuroleptic. In contrast, we could not detect any effect of the pretreatments on the K_d values ($P > 0.05$). In animals with

bilateral injections of 6-hydroxydopamine into the nucleus accumbens and chronic haloperidol administration, there was a greater increase in the density of 3H -spiperone-binding sites than there was with either treatment alone, and, again, the affinity constant was not altered. The quantitatively similar effects of 6-hydroxydopamine and chronic haloperidol treatments on the B_{max} (both producing $\sim 15\%$ increase) suggested that, together, the two treatments can produce an additive increase in the receptor density.

Our findings confirm previous reports that enhanced apomorphine-induced locomotor activity follows bilateral 6-hydroxydopamine injection into the nucleus accumbens region, a phenomenon which is thought to signify post-junctional dopaminergic supersensitivity in mesolimbic targets^{6,7,17}. However, until the present study, there has been no corresponding report of an increased density of 3H -spiperone-binding sites.

Our most intriguing result is the enhancement, which is at least additive, of apomorphine-induced locomotor activity when near-total elimination of dopamine from the nucleus accumbens is coupled with prolonged exposure to haloperidol. This finding is not predicted on the basis of classical investigations of supersensitivity², because both denervation and chronic receptor blockade are thought to evoke post-junctional supersensitivity by the same route—by persistently preventing neurotransmitter action at the postsynaptic membrane. Indeed, one interpretation of our results is that chronic exposure of postsynaptic elements in the nucleus accumbens to the antagonist in the absence of any appreciable neurotransmitter could, in its own right, trigger some of the adaptations comprising supersensitivity. This is supported by the independent elevations of nucleus accumbens dopaminergic (D-2)¹⁸ receptor densities secondary to denervation and long-term receptor

Fig. 2 Effect of various doses of apomorphine-HCl on locomotor activity. Note that the dose 329 nmol per kg corresponds to 0.1 mg per kg apomorphine-HCl. Values are the cumulative number of photocell beam interruptions (mean \pm s.e.m.) for the 60 min following apomorphine administration. Symbols and number of subjects in each group as in Fig. 1 legend. Subjects were allowed to habituate to the testing apparatus for 60–90 min before apomorphine injection. One day after the behavioural tests were completed, all subjects were decapitated for analysis of dopamine and metabolite levels in nucleus accumbens. The nucleus accumbens were dissected from a coronal slice over ice as described previously²² (wet wt ~ 8 mg) and immediately homogenized in 0.5 ml (~ 60 vols) of 0.1 M $HClO_4$ (containing 1 M $NaHSO_3$). After sonication, aliquots of each sample were centrifuged and purified by elution from alumina columns. Analysis was completed using HPLC (for details, see ref. 23). Dopamine levels (ng per mg protein) were as follows: control, 62.4 ± 5.6 ; haloperidol, 63.7 ± 3.9 ; 6-hydroxydopamine, 1.33 ± 0.21 (98% loss compared with control); 6-hydroxydopamine + haloperidol, 1.85 ± 0.52 (97% loss compared with haloperidol).

Fig. 3 Density of nucleus accumbens ^3H -spiroperone-binding sites as a function of treatment history. The nucleus accumbens were isolated (Fig. 2 legend) separately for each animal, homogenized in 1.5 ml of 10 mM Tris-maleate (with 0.9% NaCl, pH 7.5) and spun for 10 min at 20,000g at 4°C. Pellets were resuspended in 12 ml (mean final protein concentration, 60.0 μg per 900 μl) of 20 mM Tris buffer (with 0.9% NaCl, pH 7.5) using a Polytron (setting 5). An aliquot of the suspended membranes (900 μl) was combined with 100 μl of a solution containing ^3H -spiroperone (final concentrations 0.08–1.5 nM; six points in singlet for each subject) or the radioligand plus (+)butaclamol (final concentration 2 μM) to define the nonspecific binding. Further details of the binding procedure are described elsewhere²⁴. Average specific c.p.m. bound in control group binding curves were 167 and 669 for 0.08 and 1.5 nM ^3H -spiroperone respectively. B_{max} (corrected for protein²⁵) and K_d values were determined for each animal using Scatchard analysis¹⁶ and linear regression (correlation coefficients were 0.86–0.99). Control K_d values were 254 ± 24.1 pM. A recent investigation²⁶, including pharmacological characterization of ^3H -spiroperone-binding sites in the nucleus accumbens-olfactory tubercle and regional study of chronic neuroleptic-induced increases in the density of those sites strongly suggest that nucleus accumbens membrane sites labelled by this radioligand are of the dopaminergic D-2 class¹⁸ that has been characterized in the neostriatum. Thus, the nucleus accumbens sites are chiefly non-serotonergic^{27,28}. Pretreatments are as described in Fig. 1 legend, except that haloperidol was administered for 14 days. Values are the mean \pm s.e.m., n in parentheses.

blockade (see Fig. 3 legend for comments on ^3H -spiroperone binding in nucleus accumbens). It is interesting to note that acute haloperidol administration was found to decrease acetylcholine content in the corpus striatum after the elimination of the dopaminergic input¹⁹.

Because haloperidol is known to increase dopamine release which could, in part, compensate for postsynaptic receptor blockade, it could be argued that chronic haloperidol by itself does not lead to maximal supersensitivity and that dopaminergic denervation merely gives rise to the full expression of haloperidol-induced supersensitivity. However, this explanation is extremely unlikely. Because dopamine and haloperidol compete for postsynaptic receptor sites, a greater daily dose of haloperidol might be expected to produce greater postsynaptic receptor blockade and, thus, greater supersensitivity, if other factors were equal. However, it was demonstrated²⁰ that a substantially higher dose of haloperidol than we used did not produce a greater elevation of dopamine receptors, and, furthermore, haloperidol-induced dopamine utilization in rat nucleus accumbens has been shown to be reduced as the magnitude of the repeated doses is raised over a 10-fold range (0.5–5 mg per kg)²¹. Thus the idea that haloperidol-lesion-induced postsynaptic blockade is sub-maximal due to the ability of the antagonist to elevate dopamine release is unsupportable.

The marked enhancement of behavioural supersensitivity following combined denervation and chronic receptor blockade in our studies is therefore probably the result of potentiated

postjunctional supersensitivity phenomena in the nucleus accumbens. Furthermore, the increase in receptor density induced by haloperidol in 6-hydroxydopamine-treated rats cannot be located on presynaptic dopamine terminals, demonstrating that the supersensitive response to both treatments must be located on postsynaptic elements. It will be interesting to investigate the generality of these phenomena by analogous testing in other neurotransmitter systems.

Enkephalin opens potassium channels on mammalian central neurones

John T. Williams, Terrance M. Egan & R. Alan North

Neuropharmacology Laboratory, Department of Nutrition and Food Science, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139, USA

Enkephalin and opiate analgesic drugs exert their effects on the brain by interacting with receptors located on neuronal membranes. An almost immediate consequence of this interaction is an inhibition of action potential discharge of individual nerve cells¹. This could result from a direct hyperpolarization of the neurone which bears the opiate receptors, thereby shifting its membrane away from the threshold for action potential generation. On the other hand, it is well known that opiates and enkephalin depress the release of neurotransmitters^{2,3}, and this could indirectly result in an inhibition of cell firing. Here we describe experiments which indicate that Met⁵-enkephalin and a stable analogue, D-Ala²-D-Leu⁵-enkephalin (DADLE), as well as narcotic analgesics, increase the potassium conductance of neurones in the rat locus coeruleus and thereby inhibit their spontaneous firing. This effect of the opioids results from an interaction with a receptor having a high affinity for naloxone.

Fig. 1 Enkephalin inhibits cell firing. The figure shows an intracellular recording from a spontaneously firing locus coeruleus neurone. DADLE was applied by a brief (50 ms) pulse of pressure (70 kN m^{-2} , 10 p.s.i.) to a pipette positioned just above the brain slice at the times indicated by the arrows. The cell hyperpolarized and the action potential discharge was inhibited. The pen recorder did not reproduce the full action potential amplitude, which was 70–100 mV among different neurones. These recordings were made from a completely submerged slice of pons (thickness $\sim 300 \mu\text{m}$) continuously superfused with a solution of the following composition (nM): NaCl 126, KCl 2.5, CaCl_2 2.4, NaH_2PO_4 1.2, MgCl_2 1.3, NaHCO_3 25, glucose 11, which was equilibrated at 37°C with 95% O_2 , 5% CO_2 .

We studied the effects of opiates and enkephalin on neurones in the nucleus locus coeruleus. This is a compact group of noradrenaline-containing cell bodies which lies close to the floor of the fourth ventricle of the mammalian brain. Its widespread projections allow it to influence many brain regions, several of which have been implicated in the acute responses to opiates. Moreover, the locus coeruleus of the rat has a high density of opiate-binding sites, and enkephalin-like material has been localized in nerve terminals making synaptic contacts with locus coeruleus neurones⁴. It is known that opiates and enkephalin inhibit the firing of these neurones^{5–7}, and a previous study in the guinea pig indicated that this is due to a membrane hyperpolarization⁸. Intracellular recordings were made from locus coeruleus neurones in $300 \mu\text{m}$ -thick slices of brain tissue cut from the rat pons (see refs 8, 9). Drugs were added to the artificial cerebrospinal fluid solution which continuously superfused the brain slice (see Fig. 1 legend). In addition, normorphine, Met⁵-enkephalin and DADLE were administered by brief application of pressure to a micropipette containing the compound positioned just above the surface of the brain slice.

Most locus coeruleus neurones fired action potentials spontaneously at frequencies of 1–4 Hz, which is similar to their behaviour *in vivo*^{5,6}. Enkephalin and morphine each caused a concentration-dependent inhibition of this firing and a membrane hyperpolarization when added to the solution which superfused the slice (Fig. 1). The minimum concentration which inhibited firing was 10 nM, and the hyperpolarizations (mV, mean \pm s.e.m.) from the resting potential were: for normorphine ($1 \mu\text{M}$), 10.2 ± 1.2 ($n = 12$); normorphine ($10 \mu\text{M}$), 18.3 ± 4.4 ($n = 3$); DADLE (300 nM), 7.8 ± 1.8 ($n = 6$); and DADLE ($1 \mu\text{M}$), 15.6 ± 3.9 ($n = 7$). When the perfusion with morphine was continued for over 1 h the membrane remained hyperpolarized throughout, and rapidly recovered its original resting level when the drug was washed out. Application of Met⁵-enkephalin, DADLE or normorphine by the pressure technique gave hyperpolarizations of a more rapid time course which were dose-dependent, and which could be evoked reproducibly over periods of several hours (Fig. 1).

Several findings indicate that this inhibition of firing and hyperpolarization results from an increase in the K^+ ion conductance. (1) The conductance of the cell measured by passing small current pulses was increased during the opioid hyperpolarization (Fig. 2). This increase in conductance occurred

Fig. 2 Enkephalin increases membrane conductance. The upper trace is the membrane potential (resting potential -67 mV); lower trace is the transmembrane current passed by means of a bridge circuit. **A**, DADLE was applied at the arrow by pressure [two 50-ms pulses, 35 kN m^{-2} (5 p.s.i.)]. In **a**, DADLE hyperpolarized the membrane and reduced membrane resistance. In **b** the DADLE hyperpolarization was annulled by passing inward current. **B**, a similar experiment with superfusion of DADLE ($1 \mu\text{M}$) during the period indicated. The apparent delay in onset of the hyperpolarization is due to passage through the perfusion system. Restoration of the membrane potential to its control level allowed separation of the DADLE-induced resistance change and membrane rectification. In experiments of this type the amplitude of the enkephalin (or normorphine)-induced resistance changes was correlated with the potential change (ΔV) and used to estimate the response reversal potential $E_{\text{rev},R}$ from $\Delta V = (1 - R'/R)(E_{\text{rev},R} - E_m)$ where E_m is the membrane potential before application of enkephalin, R is the control input resistance, and R' is the input resistance at peak enkephalin effect, measured after restoring the potential E_m (as in **b**). $E_{\text{rev},R}$ was -135.5 ± 7.5 (mean \pm s.e.m., $n = 11$) for pressure application, and -124.0 ± 8.1 ($n = 10$) for perfusion. These values were always more negative than those estimated by changing E_m (see Fig. 3). E_{rev} was also estimated from $\Delta V = (1 - \tau'/\tau)(E_{\text{rev},\tau} - E_m)$ where τ' and τ are time constants of small hyperpolarizing current pulses. $E_{\text{rev},\tau}$ was $-103 \pm 5.9 \text{ mV}$ ($n = 10$) with application of opioids by perfusion. $E_{\text{rev},\tau}$ is relatively insensitive to the location of the conductance increase¹⁵, whereas $E_{\text{rev},R}$ will be an overestimate of E_{rev} if the conductance change significantly affects electronically distant membrane. This indicates that enkephalin increases the conductance of both the soma and the dendrites.

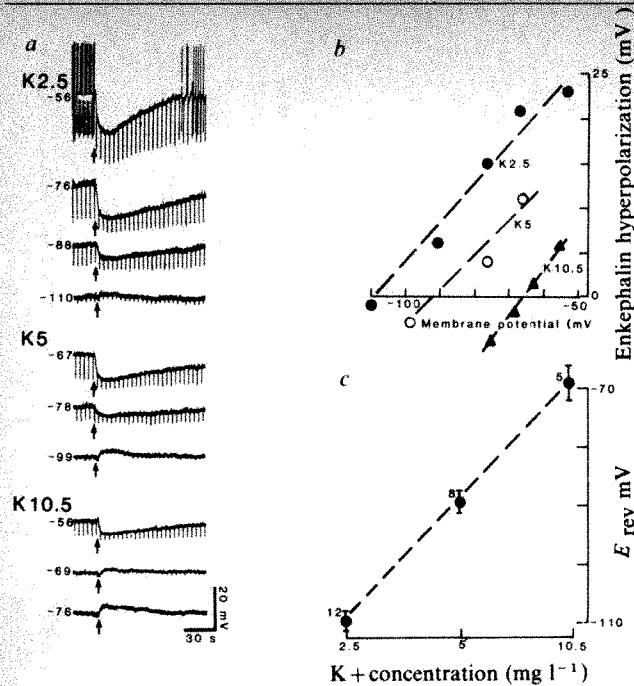

Fig. 3 Enkephalin opens potassium channels. *a* DADLE was applied by pressure [arrow, 50-ms pulse 70 kN m⁻² (10 p.s.i.)] at various membrane potentials. The potassium concentration was as indicated (K, mM). At elevated K⁺ concentrations, the enkephalin response reversed polarity with membrane hyperpolarization. Note the marked rectification occurring with hyperpolarization and with elevated K⁺ concentration. *b* Relationship between hyperpolarization amplitude and membrane potential. *c*, Enkephalin reversal potential (E_{rev}) calculated from many experiments such as those in *a* and *b*. The broken line is $E_{rev} = RT/F \ln([K]_o/[K]_i)$, where $[K]_i$, the intracellular K⁺ concentration, was taken as 145 mM. (In normal potassium solutions (2.5 mM), it was usually not possible to reverse the enkephalin hyperpolarization, therefore extrapolated values were used.) The good agreement between the observed values of E_{rev} and those predicted from the Nernst equation suggests a predominantly somatic site of action; the large steady-state conductance increase which accompanied membrane hyperpolarization would effectively remove the dendritic contribution (see Fig. 2 legend).

both on the neurone soma and dendrites (see Fig. 2 legend). (2) The enkephalin hyperpolarization became smaller when it was evoked at hyperpolarized resting membrane potentials, and the response reversed polarity at ~ -105 mV (Fig. 3). Complete reversal of the hyperpolarization was often not possible, presumably because of the dendritic site of action combined with strong rectifying properties of the membrane (Fig. 3). The extrapolated reversal potentials followed the K⁺ equilibrium potential (E_K) when the extracellular K⁺ concentration was altered (Fig. 3). (3) Intracellular injection of Cs⁺ or extracellular application of Ba²⁺ both rapidly abolished the opioid hyperpolarizations. (4) The opioids prolonged the after-hyperpolarizations which followed a burst of action potentials; this after-hyperpolarization is due to an increase in K⁺ conductance triggered by Ca²⁺ entry during the action potentials (J.T.W. and R.A.N., unpublished observations). (5) Finally, Cl⁻ movement probably does not contribute to the response because opioid hyperpolarizations were observed equally well with intracellular electrodes containing chloride, methylsulphate or citrate anions, and because chloride-dependent hyperpolarizations induced by γ -aminobutyric acid reversed to depolarizations after a period of recording with chloride-filled electrodes, whereas opiate hyperpolarizations did not change.

The opiate-induced K⁺ activation was apparently voltage-dependent: at potentials less negative than the resting potential (which was -55 to -60 mV), the amplitude of the enkephalin hyperpolarization declined sharply. This decrease in effect was not related to the fact that the cells were firing rapidly at such depolarized potentials—similar effects were observed when spontaneous firing was abolished in solutions containing tetrodotoxin and cobalt. This voltage-dependence is similar to that of the K⁺ activation by acetylcholine on autonomic ganglion cells¹⁰ and of the K⁺ activation by intracellular Ca²⁺ in myenteric neurones¹¹. It allows maximum effect of opiates at membrane potentials close to threshold.

The hyperpolarization induced by opiates was essentially unchanged in calcium-free solutions, as was previously observed^{8,12}. Thus their action is not due to release of other transmitters which then increase the K⁺ conductance of the impaled neurone.

The opiate antagonist naloxone reversibly inhibited the action of opiates. Because of the high reproducibility of the

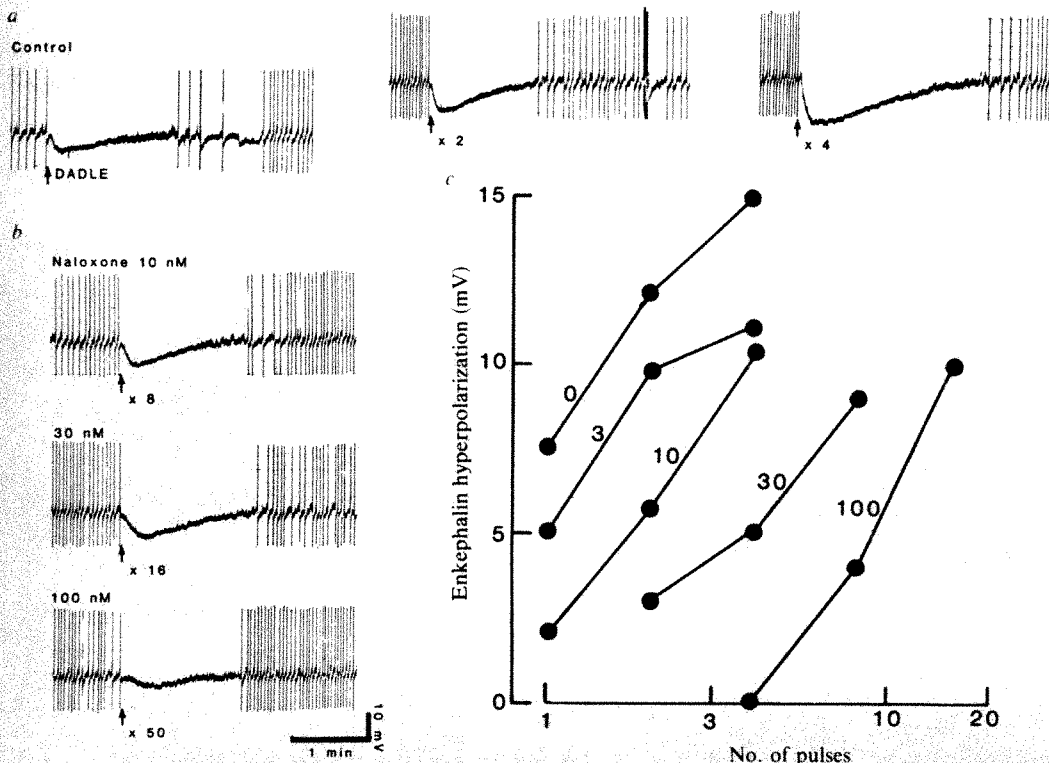

Fig. 4 Enkephalin interacts with naloxone-sensitive receptor. *a*, Control dose-response curve to DADLE applied by pressure (arrow, 24 ms, 55 kN m⁻² (8 p.s.i.), number of pulses indicated). *b*, Selected records from similar dose-response curves in the presence of various concentrations of naloxone. *c*, Dose-response curves to DADLE at the concentrations of naloxone indicated (nM). A response level was chosen so as to minimize interpolative errors and a Schild¹⁶ plot was used to calculate the dissociation equilibrium constant.

hyperpolarization induced by pressure application, we were able to demonstrate that this action of naloxone was competitive for dose ratios up to at least 64 (Fig. 4). The dissociation equilibrium constant for naloxone determined from such studies was 1.5 nM (95% confidence limits 2.1–1.1 nM, $n=4$) which is close to that found in radioactive ligand-binding studies with brain membranes prepared by homogenization. This implies that the affinity of the opiate-binding sites for naloxone determined in such biochemical experiments may be close to that found on functioning neurones.

The opening of K^+ channels by opiates may underlie not only the inhibition of cell firing but could contribute to the reduced transmitter release observed in several preparations^{2,3,13}. Transmitter release might be inhibited if the K^+ activation reduced spike duration and resulted in less Ca^{2+} entry, or if the increase in K^+ conductance caused block of impulse propagation at varicosities¹⁴. Which of these two actions predominates may depend largely on the part of the nerve cell involved, the region of the nervous system examined and on the experimental or physiological conditions, but both would contribute to the depression of the nervous system which is the hallmark of opiate action.

Predominance of the amino-terminal octapeptide fragment of dynorphin in rat brain regions

Eckard Weber, Christopher J. Evans & Jack D. Barchas

Nancy Pritzker Laboratory of Behavioral Neurochemistry, Department of Psychiatry and Behavioral Sciences, Stanford University School of Medicine, Stanford, California 94305, USA

Dynorphin is a 17 amino acid opioid peptide which was originally isolated and characterized from pig neurohypophysis and gut extracts^{1–3}. It contains a leucine-enkephalin (Leu-enkephalin) sequence at the amino terminus and has an unusually potent *in vitro* opiate activity in the guinea pig ileum longitudinal muscle/myenteric plexus preparation^{1,4}. Immunohistochemical studies have shown that perikarya, nerve fibres and terminals widely distributed throughout the central nervous system^{5,6} are immunoreactive for both dynorphin_{1–17} and α -neo-endorphin^{6,7}, another Leu-enkephalin-containing opioid peptide which is structurally related to dynorphin (Fig. 1) and was isolated from hypothalamus⁸. But although the regional distributions of α -neo-endorphin and dynorphin_{1–17} in rat brain, as measured by radioimmunoassay (RIA), are similar, the molar ratio of the two peptides seems to vary greatly from region to

region, with α -neo-endorphin being present in much higher concentrations than dynorphin_{1–17}^{9–11}. We now report that dynorphin_{1–8}, an amino-terminal fragment (Fig. 1), which has only ~3% of the opioid potency of dynorphin_{1–17}, (ref. 4), is present in up to 10-fold higher concentrations in brain than dynorphin_{1–17} immunoreactivity. We further show that dynorphin_{1–8}, but not dynorphin_{1–17}, occurs in approximately equimolar concentrations with α -neo-endorphin in all brain regions examined, suggesting a close biosynthetic relationship between α -neo-endorphin and dynorphin_{1–8}.

The various peptides were detected in acid acetone extracts of rat brain regions with three different highly specific RIAs using antibodies raised against synthetic dynorphin_{1–17}, dynorphin_{1–8} and α -neo-endorphin. All the RIAs were highly specific for their respective antigen. There was no significant cross-reactivity with related peptides or with the peptides recognized by the other RIAs (Table 1).

When extracts from rat brain regions were analysed using the α -neo-endorphin and dynorphin_{1–17} RIAs, the immunoreactivities for the two peptides were found to have a similar distribution, however, α -neo-endorphin immunoreactivity was present in much higher concentrations than dynorphin_{1–17} immunoreactivity and, more important, the molar ratio of α -neo-endorphin to dynorphin_{1–17} was extremely variable among brain regions (Table 2). This finding seemed to be inconsistent with the close biosynthetic relationship between the two peptides suggested by our initial immunohistochemical observations of the two substances in the same neurones^{6,7}.

Table 1 Specificity of RIAs used to detect dynorphin_{1–17}, dynorphin_{1–8} and α -neo-endorphin in extracts of rat brain regions

Synthetic peptide	% Cross-reactivity in RIA for		
	Dynorphin _{1–17}	Dynorphin _{1–8}	α -Neo-endorphin
Dynorphin _{1–17}	100	<0.001	0
Dynorphin _{1–8}	0	100	0
α -Neo-endorphin	0	0	100
Leu-enkephalin	0	0	0
Dynorphin _{1–6}	0	0	0
Dynorphin _{1–7}	0	0.001	0
Dynorphin _{1–9}	<0.001	0.01	0
Dynorphin _{1–13}	50	0.001	0
Dynorphin _{6–17}	0	0	0
β -Neo-endorphin	0	0	<0.01
α -Neo-endorphin _{1–8}	0	0	0

RIAs were carried out as described in Table 2 legend. The cross-reactivity was calculated based on the amounts of unlabelled peptide needed to obtain a 50% displacement of ¹²⁵I-labelled peptide from the antisera. The highest concentration of unlabelled peptide tested was 1 μ M. When the displacement was <50% at 1 μ M concentration, the cross-reactivity calculations were based on the amount of displacement obtained at this concentration. (Synthetic peptides were solid phase synthesized and purified by Dr J.-K. Chang, Peninsula Laboratories.)

Earlier studies, however, had identified an amino-terminal octapeptide fragment of dynorphin, dynorphin_{1–8}, in hypothalamus and posterior pituitary^{12,13}. We reasoned that if dynorphin_{1–8} were a major product in a biosynthetic pathway involving dynorphin_{1–17} as a precursor or intermediate, then by using antibodies to dynorphin_{1–17} we would greatly underestimate the actual amounts of dynorphin-like molecules present because the antibodies would not detect dynorphin_{1–8} (Table 1). When we measured dynorphin_{1–8} immunoreactivity in brain region extracts, it was indeed found that most of the dynorphin-like peptides corresponded to dynorphin_{1–8}-immunoreactive material with up to 10-fold more dynorphin_{1–8} than dynorphin_{1–17} immunoreactivity (Table 2). By comparing the amounts

Fig 1 Amino acid sequences of the structurally related opioid peptides dynorphin_{1–17} (a) and α -neo-endorphin (b) (refs 2, 8)

of dynorphin₁₋₈ and α -neo-endorphin immunoreactivity we concluded that an approximately 1:1 molar ratio of dynorphin₁₋₈ and α -neo-endorphin immunoreactivity exists in all brain regions examined (Table 2).

We estimated the molecular size of the immunoreactive peptides by chromatographing extracts from all brain regions indicated in Table 2 on a Sephadex G-50 column in 50% acetic acid^{14,15}. In addition, immunoreactive peaks from the Sephadex G-50 profile from three regions (posterior pituitary, striatum and midbrain) were rechromatographed by reverse-phase HPLC. Figure 2a-f shows the gel-filtration profiles of hypothalamus (a-c) and striatal (d-f) extracts. In the former

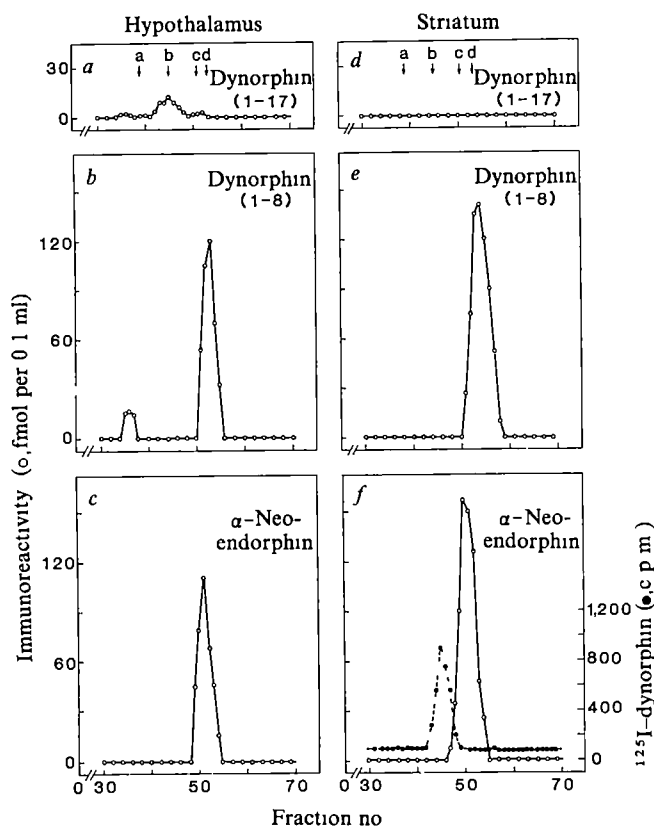

Fig 2 Gel-filtration chromatography profiles of immunoreactive dynorphin₁₋₁₇, dynorphin₁₋₈ and α -neo-endorphin in rat brain region extracts. Chromatography profiles were obtained from extracts of all brain regions indicated in Table 2. The profiles from hypothalamus (a-c) and striatal (d-f) extracts are shown. The brain regions from 10 animals were extracted with acid acetone as described in Table 2 legend. The supernatants of the acid acetone extracts were subjected to lipid extraction with 10 vol of heptane. In pilot experiments, it was found that ¹²⁵I-labelled dynorphin₁₋₁₇, dynorphin₁₋₈ and α -neo-endorphin did not enter the heptane phase but remained completely in the acid acetone phase. The heptane phases were discarded and the acid-acetone phases evaporated to dryness under a stream of air. The residues were taken up in 1 ml of 50% acetic acid and insoluble material was removed by centrifugation. The supernatants were subjected to gel-filtration chromatography at room temperature on a 120 cm × 0.9 cm column packed with Sephadex G-50 fine resin swollen and equilibrated in 50% acetic acid. Elution of Sephadex G-50 in 50% acetic acid, a strongly dissociating agent, eliminates nonspecific interactions of the peptides with the gel matrix and the elution volume on these columns is a strictly linear function of the logarithm of the molecular weight in the range 500–10,000 (refs 14, 15). Fractions (1.8 ml) were collected and 100- μ l aliquots were evaporated under reduced pressure and assayed in the three RIAs. The columns were calibrated with ¹²⁵I- α -N-acetyl β -endorphin (a), ¹²⁵I-dynorphin₁₋₁₇ (b), ¹²⁵I- α -neo-endorphin (c) and ¹²⁵I-dynorphin₁₋₈ (d). A trace amount of either ¹²⁵I-dynorphin₁₋₁₇ or ¹²⁵I- α -neo-endorphin was included in each run of tissue extract to control the reproducibility of the chromatography. The recovery of immunoreactivity from the columns was 88–92%. To determine whether dynorphin₁₋₈ can be formed from dynorphin₁₋₁₇ as an artefact during extraction, a trace amount of ¹²⁵I-labelled dynorphin₁₋₁₇ was added to the extractant immediately before homogenization of striatum, one of the regions with the largest excess of dynorphin₁₋₈ over dynorphin₁₋₁₇ (Table 2). Figure 1f shows that all the radioactivity from this experiment eluted at the position of ¹²⁵I-dynorphin₁₋₁₇. No radioactivity above background eluted at the position of ¹²⁵I-dynorphin₁₋₈.

Fig 3 Reverse-phase HPLC of immunoreactive dynorphin₁₋₈ from rat midbrain extracts. Extracts were prepared and separated on a Sephadex G-50 column in 50% acetic acid as described in Fig 2 legend. A 500- μ l aliquot from the dynorphin₁₋₈ immunoreactive peak fraction was evaporated under a stream of nitrogen, taken up in HPLC buffer (see below) and chromatographed on an Altex Ultrasphere ODS column (250 mm × 4.6 mm, particle size 5 μ m). Two Altex HPLC pumps and a Beckman gradient mixing computer were used to generate a four-step acetonitrile gradient as shown in the graph. The HPLC buffer consisted of 50 mM monosodium phosphate, 1 mg ml⁻¹ phosphoric acid and 5% methanol, pH 2.7. The flow rate was 1.5 ml min⁻¹ and 1-min fractions were collected. Aliquots (500 μ l) of the fractions were evaporated first under a stream of air to remove the acetonitrile and then under reduced pressure. The residues were assayed in the dynorphin₁₋₈ RIA. Most (>95%) of the immunoreactivity eluted at exactly the same position as synthetic dynorphin₁₋₈, whereas a minor immunoreactive peak of unknown nature eluted at a higher acetonitrile concentration. The co-migration of the immunoreactivity with the synthetic standard was assessed in two ways: (1) the elution of the immunoreactive peak was compared with the elution of the synthetic peptide in a separate run as detected by optical density measurements at 210 nm, and (2) an aliquot from the immunoreactive peak fraction was 'spiked' with an equimolar amount of the synthetic peptide and rechromatographed. In the spiking experiment, the total immunoreactivity eluted as one single peak. When α -neo-endorphin immunoreactive material from the Sephadex G-50 columns was rechromatographed by reverse-phase HPLC we found, as have two other groups^{10,11}, that this material eluted at exactly the same position as synthetic α -neo-endorphin (not shown). An isocratic step was included in the elution profile between fractions 25 and 50 to improve the separation of dynorphin₁₋₈ from β -neo-endorphin. Markers: a, α -neo-endorphin; b, β -neo-endorphin; c, dynorphin₁₋₈; d, dynorphin₁₋₁₇.

extract (a-c), the material detected by the dynorphin₁₋₁₇ RIA constituted only a fraction of the material detected by the dynorphin₁₋₈ or α -neo-endorphin RIA. In the fractionated striatal extracts, dynorphin₁₋₁₇ immunoreactivity was below the detection limits of the various RIAs whereas dynorphin₁₋₈ and α -neo-endorphin immunoreactivities were readily detectable (Fig 2d-f). For all brain regions, the major immunoreactive peaks for α -neo-endorphin and dynorphin₁₋₈ eluted at exactly the same position as the respective ¹²⁵I-labelled synthetic marker peptides (Fig 2a-f). Rechromatography by reverse-phase HPLC of the major α -neo-endorphin and dynorphin₁₋₈ immunoreactive peaks from three brain regions (posterior pituitary, striatum, midbrain) showed that the immunoreactivity detected by the α -neo-endorphin and dynorphin₁₋₈ RIAs co-migrated exactly with their respective synthetic marker peptide (Fig 3).

We conclude that dynorphin₁₋₈ is neither an extraction artefact nor a product of extraneuronal metabolism of dynorphin₁₋₁₇ as (1) when ¹²⁵I-labelled dynorphin₁₋₁₇ was added to the tissue at the time of extraction, no conversion of this radioactive marker to dynorphin₁₋₈ was observed (Fig 2f), (2) the amounts of dynorphin₁₋₁₇ which we measured are similar to those reported by other groups^{9,11}, and (3) synthetic dynorphin₁₋₁₃ added to washed brain membranes or injected *in vivo* into the brain ventricles is degraded primarily at the amino terminus by aminopeptidases^{16,17}.

The results presented here suggest a precursor-product relationship between dynorphin₁₋₁₇ and dynorphin₁₋₈. It is possible that dynorphin₁₋₈ is derived from a different precursor

Table 2 Concentration and molar ratios of dynorphin₁₋₁₇, dynorphin₁₋₈ and α -neo-endorphin immunoreactivities in rat brain regions

	Immunoreactivity (pmol per g tissue)			Molar ratios		
	Dynorphin ₁₋₁₇	Dynorphin ₁₋₈	α -Neo-endorphin	D ₁₋₈ /D ₁₋₁₇	α -Neo/D ₁₋₁₇	α -Neo/D ₁₋₈
Medulla/pons	3.9 ± 0.4	22.5 ± 0.6	26.3 ± 1.1	5.7	6.6	1.2
Midbrain	6.2 ± 1.0	59.6 ± 3.7	59.7 ± 2.0	9.6	9.6	1.0
Cerebellum	<0.2	<1.2	<1.7			
Spinal cord	12.1 ± 2.3	22.7 ± 1.6	26.5 ± 2.0	1.9	2.2	1.2

Hippocampus	3.4 ± 0.7	26.5 ± 2.2	25.6 ± 1.4	7.9	7.6	1.0
Hypothalamus	10.3 ± 1.1	65.5 ± 1.8	76.7 ± 5.7	6.4	7.5	1.2
Posterior pituitary	503.6 ± 32.9	1384.0 ± 84.4	1598 ± 117.9	2.8	3.2	1.1

Brain regions were dissected from 10 male Sprague-Dawley rats (160–180 g) as described in ref. 20. The tissue was frozen immediately on dry ice. After weighing in the frozen state, each tissue sample was individually extracted by sonication in 1 ml of acid acetone (acetone/water 12 M HCl, 40:6:1). The homogenates were centrifuged at 12,000g for 10 min and supernatants were evaporated to dryness under a stream of air in silanized glass tubes. The residue was taken up in 1 ml of RIA buffer and after further centrifugation aliquots of the supernatants were appropriately diluted and assayed in the three RIAs. The RIA procedure was that described in ref. 14, with modifications: the use of a buffer pH of 7.4 rather than 6.0, and application of a double antibody separation procedure rather than a dextran-coated charcoal separation. Antiserum dilutions were 1:130,000, 1:120,000 and 1:30,000 for the dynorphin₁₋₁₇, dynorphin₁₋₈ and α -neo-endorphin RIAs respectively. Values are expressed as corrected means \pm s.e.m. from determinations of the brain regions from 10 individual animals. The measured values were corrected for recovery. The recovery for each peptide from each brain region was determined in separate experiments by adding a trace amount of ¹²⁵I-labelled synthetic peptide to the extractant immediately before homogenization of the sample. After all steps of repeated centrifugation, evaporation and rehydration, the amount of recovered radioactivity was 59 \pm 2.3%, 70 \pm 4.1% and 73 \pm 3.3% for dynorphin₁₋₁₇, dynorphin₁₋₈ and α -neo-endorphin respectively. Measurements of the three peptides were repeated twice on two groups of brains from 13 and 6 animals. Brain regions from the 13 animal group were also extracted into acid acetone while the samples from the 6 animal group were extracted into 1 ml each of 0.1 M HCl at 95 °C. The supernatant of the 0.1 M HCl extract was neutralized with an equal volume of 0.1 M NaOH and appropriate dilutions were assayed directly in the RIAs. The results from these two experiments were essentially identical to those shown in the table.

However, previous work showing that α -neo-endorphin and dynorphin₁₋₁₇ immunoreactivities occur within the same neurones^{6,7} and the finding that α -neo-endorphin and dynorphin₁₋₈, but not dynorphin₁₋₁₇, occur in equimolar concentrations throughout the brain suggest that dynorphin₁₋₁₇ is a precursor or intermediate in the formation of dynorphin₁₋₈. A precursor role of dynorphin₁₋₁₇ would explain the rather low concentrations of this peptide in brain. Furthermore, the equimolar distribution of dynorphin₁₋₈ and α -neo-endorphin in all brain regions examined raises the possibility that the two peptides are major products in the processing of a larger common precursor. However, only isolation of such a prohormone or its mRNA can assign a common biosynthetic origin of the two peptides.

The function of dynorphin₁₋₁₇ in brain as an opiate peptide must be re-evaluated in view of the present findings. Dynorphin₁₋₈, the predominant dynorphin-like peptide in brain is far less potent than its putative precursor dynorphin₁₋₁₇ (ref. 4). Given these significant differences in opiate potency of the two peptides, the finding that the ratio of dynorphin₁₋₈ to dynorphin₁₋₁₇ immunoreactivity varies greatly among brain regions, ranging from 2:1 in the spinal cord to 10:1 in the midbrain and striatum (Table 2), may reflect region-specific physiological differences in processing. Certain neuronal populations may leave relatively more dynorphin₁₋₁₇ intact in some regions, thus increasing dramatically the available pool of opiate potency and specificity towards certain receptor types^{18,19}, whereas other neuronal populations may inactivate much of this opiate activity simply by converting dynorphin₁₋₁₇ more completely into dynorphin₁₋₈. Future studies will determine whether external stimuli can significantly alter this processing pattern.

This work was supported by NIDA grant DA 01207 and a Selected Research Opportunity from the ONR (SRO 001 N00014-C-0796). We thank Pamela Angwin and Irene Inman for help with the RIAs and S. Poage for preparing the manuscript.

Dynorphin₁₋₈ and dynorphin₁₋₉ are ligands for the κ -subtype of opiate receptor

Alistair D. Corbett, Stewart J. Paterson,
Alexander T. McKnight, Jacques Magnan

Unit for Research on Addictive Drugs, University of Aberdeen,
Marischal College, Aberdeen AB9 1AS, UK

It is generally accepted that there are three subtypes of opiate receptor: μ , δ and κ . The main endogenous ligands for the μ - and δ -sites are Met⁵-enkephalin, Leu⁵-enkephalin and β -endorphin, whereas the putative endogenous ligands for the κ -binding site were unknown until recent observations suggested that dynorphin₁₋₁₃ might be a candidate. The most convincing evidence for this view has been presented by Goldstein and his colleagues who showed that dynorphin₁₋₁₃ is a specific endogenous ligand for the κ -receptor and has a high potency and long duration of action¹⁻³. We show here that the sequences Leu⁵-enkephalyl-Arg-Arg-Ile (dynorphin₁₋₈) and, particularly, Leu⁵-enkephalyl-Arg-Arg-Ile-Arg (dynorphin₁₋₉) are selective ligands for the κ -binding site. Whereas dynorphin₁₋₁₃ and dynorphin₁₋₁₇ are relatively resistant to the action of peptidase and have a long duration of action *in vitro* after wash-out, dynorphin₁₋₈ and dynorphin₁₋₉ are readily degraded by peptidases and their duration of action is much shorter. For this and other reasons, the possibility will have to be considered that dynorphin₁₋₈ or dynorphin₁₋₉ may be transmitters or modulators at the κ -binding site while dynorphin₁₋₁₃ and dynorphin₁₋₁₇ may act hormonally, that is, at a distance from the site of release.

Table 1 Inhibitory effects of C-terminally extended Leu⁵-enkephalins on the electrically induced contractions of the guinea pig myenteric plexus-longitudinal muscle and the vasa deferentia of the mouse, rat and rabbit

C-terminal extensions of Leu ⁵ -enkephalin	IC ₅₀ (nM)			
	Guinea pig myenteric plexus	Mouse vas deferens	Rat vas deferens	Rabbit vas deferens
—	28.6 ± 5.4	1.7 ± 0.3	550 ± 62	>10,000
Lys ⁶	107 ± 29.1	25.6 ± 4.9	720 ± 45	>10,000
Arg ⁶	102 ± 17.2	10.9 ± 1.1	790 ± 46	3,000 ± 930
Arg ⁶ -Arg ⁷	17.3 ± 2.52	25.5 ± 4.2	7,500 ± 2,000	43.0 ± 11.5
Arg ⁶ -Arg ⁷ -Ile ⁸	4.92 ± 0.53	9.2 ± 1.30	>10,000	11.7 ± 1.27
Arg ⁶ -Arg ⁷ -Ile ⁸ -Arg ⁹	2.36 ± 0.67	6.5 ± 0.34	>10,000	6.1 ± 0.45
Dynorphin ₁₋₁₃	0.31 ± 0.16	0.33 ± 0.08	>10,000	2.43 ± 0.49
Dynorphin ₁₋₁₇	0.29 ± 0.09	0.91 ± 0.13	>10,000	3.01 ± 1.6
α-Neo-endorphin	2.98 ± 0.44	7.7 ± 0.98	>10,000	21.4 ± 4.5

The values shown are the mean ± s.e.m. of three to four observations. The activity of peptidases has been inhibited by bestatin (10 μM, or 30 μM in the rat and rabbit), L-leucyl-L-leucine (2 mM), thiorphan (0.3 μM) and captopril (10 μM), in the rabbit vas deferens, this treatment increased the potency of the enzyme-sensitive peptides, but not of dynorphin₁₋₁₃ or dynorphin₁₋₁₇, 60–270-fold. The sequence of dynorphin is Tyr-Gly-Gly-Phe-Leu-Arg-Arg-Ile-Arg-Pro-Lys-Leu-Lys-Trp-Asp-Asn-Gln and of α-neo-endorphin is Tyr-Gly-Gly-Phe-Leu-Arg-Lys-Tyr-Pro-Lys. The peptides were obtained from Peninsula, Bachem and Cambridge Research Biochemicals or were gifts from Drs A. Goldstein, J. Morley and S. Udenfriend.

Our results were obtained from four *in vitro* pharmacological assays in which the preparations were made to contract by electrical stimulation. The preparations respond differently to activation of the μ-, δ- and κ-receptors. The inhibitory potencies of the peptides are given as their 50% inhibitory concentration (IC₅₀, nM) values. In the myenteric plexus-longitudinal muscle of the guinea pig ileum, an inhibitory effect is readily observed with ligands that activate μ- and κ-receptors, whereas the mouse vas deferens responds preferentially to ligands acting on δ-receptors⁴, the vas deferens of the rat has a low sensitivity to κ-ligands⁵ in contrast to the vas deferens of the rabbit in which κ-ligands, but not μ- or δ-ligands, are inhibitory^{6,7}. In these assays, the activity of peptidases was inhibited by a mixture of bestatin, L-leucyl-L-leucine, thiorphan and captopril (Table 1 and A.T.McK., A.D.C. and H.W.K., unpublished observations). The peptides used in this investigation had agonist, but no antagonist, action.

The binding of the peptides was measured by determining the inhibition constants (*K*_i, nM) in three assays on homogenates of guinea pig brain. For this purpose, ³H-labelled D-Ala², MePhe⁴, Gly-ol⁵-enkephalin was used as a highly selective μ-ligand and ³H-D-Ala², D-Leu⁵-enkephalin as a δ-ligand which, although selective, has a cross-reactivity of ~10% at the μ-binding site⁸. The most suitable ligand for the assay of the κ-binding site was found to be ³H-(−)bremazocine⁹ after suppression of the binding at the μ- and δ-sites by addition of unlabelled μ- and δ-ligands at a concentration of 100 nM each.

To reduce degradation by peptidases, the binding assays were carried out at 0 °C for 150 min (Table 2).

Two groups of C-terminal extensions of Leu⁵-enkephalin have been shown to occur in the central nervous system (CNS). They are dynorphin₁₋₈ (Leu⁵-enkephalyl-Arg-Arg-Ile, refs 10, 11) and dynorphin₁₋₁₇ (refs 12, 13), which have two arginine residues in positions 6 and 7, and α- and β-neoendorphin^{14,15}, which are nona- and decapeptides respectively, with arginine and lysine residues in positions 6 and 7.

In the pharmacological assays (Table 1), the introduction of Arg⁶ or Lys⁶ at the C-terminal end of Leu⁵-enkephalin reduced its potency without altering the relative activity pattern. However, lengthening the chain from residue 7 onwards increased the ratio of IC₅₀ for the mouse vas deferens to IC₅₀ for the myenteric plexus. The most important effects of the extensions by Arg⁶-Arg⁷ or Arg⁶-Lys⁷ and beyond are the complete loss of potency in the rat vas deferens, which probably has no κ-binding sites⁵, and the progressively increasing activity in the rabbit vas deferens which responds to ketazocine- or κ-like compounds but not to μ- or δ-like ligands^{6,7}. The most potent C-extended forms of Leu⁵-enkephalin are dynorphin₁₋₁₃, dynorphin₁₋₁₇ and dynorphin₁₋₉, Leu⁵-enkephalyl-Arg-Arg-Ile-Arg (Table 1).

These findings are confirmed by the determination of the *K*_i values at the μ-, δ- and κ-binding sites (Table 2). All C-terminal extensions have lower ratios of *K*_i at the δ-binding site to *K*_i at the μ-binding site than the ratio found for the parent Leu⁵-

Table 2 The inhibitory effects of C-terminally extended Leu⁵-enkephalins on the binding in homogenates of guinea pig brain of ³H-D-Ala², MePhe⁴, Gly-ol⁵-enkephalin (1.0 nM), ³H-D-Ala², D-Leu⁵-enkephalin (1.0 nM) and ³H-bremazocine (0.30 nM)

Dynorphin ₁₋₁₇	0.73 ± 0.09	2.38 ± 0.61	0.115 ± 0.018
α-Neo-endorphin	1.24 ± 0.20	0.57 ± 0.086	0.196 ± 0.044

The values shown are the mean ± s.e.m. of three to four observations. The method used for the binding assays has been described previously⁹, incubation was for 150 min at 0 °C. ³H-(−)bremazocine (Dr Romer, Sandoz) was used instead of ³H-(±)ethylketazocine and the binding at the μ- and δ-sites was suppressed with 100 nM each of D-Ala², MePhe⁴, Gly-ol⁵-enkephalin (Dr Romer, Sandoz) and D-Ala², D-Leu⁵-enkephalin (Dr Wilkinson, Wellcome). ³H-D-Ala², MePhe⁴, Gly-ol⁵-enkephalin and ³H-D-Ala², D-Leu⁵-enkephalin were obtained from Amersham.

enkephalin. The most interesting observation, however, is the progressive increase in the affinity at the κ -binding site as Leu⁵-enkephalyl-Arg⁶-Arg⁷ (dynorphin₁₋₇) is extended by Ile⁸ (dynorphin₁₋₈) and by Ile⁸-Arg⁹ (dynorphin₁₋₉). Dynorphin₁₋₁₃ has the highest relative affinities at all three binding sites, the values being of an order similar to those described recently for the inhibition of the binding of ³H-dihydromorphine, ³H-D-Ala², D-Leu⁵-enkephalin and ³H-ethylketazocine by dynorphin₁₋₁₃ amide in guinea-pig brain³ or inhibition of the binding of ³H-ethylketazocine or ³H-diprenorphine by dynorphin₁₋₁₃ or dynorphin₁₋₁₇ in human brain¹⁶.

The findings with dynorphin₁₋₇, dynorphin₁₋₈ and particularly dynorphin₁₋₉ indicate that these fragments are potent and increasingly selective κ -ligands and therefore merit further analysis, particularly as dynorphin₁₋₈ has been identified in porcine hypothalamus¹⁰ and in the neurointermediate pituitary of the rat¹¹, and dynorphin₁₋₁₇ in rat pituitary¹² and in porcine duodenum¹³. The 'small' dynorphins are readily degraded by peptidases, an action which can be prevented by the mixture of peptidase inhibitors. In the myenteric plexus, the IC₅₀ values of dynorphin₁₋₇, dynorphin₁₋₈ and dynorphin₁₋₉ were, respectively, 367, 30.8 and 21.5 nM before treatment with the peptidase inhibitors and 17.3, 4.9 and 2.4 nM after treatment, an average potentiation of about 12, while there was no potentiation of either dynorphin₁₋₁₃ or dynorphin₁₋₁₇. Furthermore, in four experiments in the presence of the peptidase inhibitors, the recovery of the effect of dynorphin₁₋₉ on the contraction of the myenteric plexus-longitudinal muscle was rapid ($t_{1/2}$ = 48 ± 6 s) and the recovery after dynorphin₁₋₁₇ was slow ($t_{1/2}$ = 178 ± 8 s). Finally, in the rabbit vas deferens pretreated with peptidase inhibitors, the IC₅₀ value of dynorphin₁₋₈ is ~11.7 nM and that of dynorphin₁₋₁₃ 2.43 nM, while the corresponding K_1 values at the κ -binding site are 1.34 and 0.045, respectively. Thus, the 'small' dynorphins are liable to be degraded by peptidases, are easily washed out and have moderate potency at the κ -site while the 'large' dynorphins are peptidase resistant, do not wash out readily and are "extraordinarily potent"¹⁷. The small dynorphins seem to have the qualities of a neurotransmitter or neuromodulator of short and rapid action, whereas the large dynorphins have the characteristics of a highly potent hormonal action of long duration. Moreover, it is of interest that the small dynorphin found in neuronal tissue is dynorphin₁₋₈, which is a less selective κ -ligand than dynorphin₁₋₉. Note that the κ -binding site is very demanding in its choice of ligands as Met⁵-enkephalin, Leu⁵-enkephalin and β -endorphin have only low affinities¹⁸; thus, dynorphin₁₋₈, which has affinities to the μ - and δ -binding sites, is sufficiently selective as far as the κ -binding site is concerned.

An urgent requirement is confirmation or otherwise that dynorphin₁₋₈ and possibly dynorphin₁₋₉ are strong candidates for the role of an endogenous ligand at the κ -binding site mediating neurotransmission or neuromodulation. Lastly, it will be important to correlate the putative κ -like actions of the small dynorphins with the pharmacological effects of the ketazocine-like compounds or κ -agonists^{19,20} which are antinociceptive agents and yet do not substitute for morphine in the morphine-dependent rhesus monkey²¹⁻²³. It may now become possible to exploit the therapeutic potentials of this group of compounds⁸.

One of the most actively studied chemoreceptors is the acetylcholine receptor (AChR) in the postsynaptic membranes of neuromuscular junctions and electrocytes. The AChR from *Torpedo* is a membrane protein, each molecule comprising five polypeptide chains^{1,2}: two α -chains of molecular weight (M_r) 40,000, and three homologous chains of M_r 50,000 (β), 60,000 (γ) and 65,000 (δ). Only the α -subunits seem to carry the specific recognition sites for agonists and antagonists². As snake α -neurotoxins seem to bind highly specifically and quasi-irreversibly to these sites we performed a structural analysis to localize the α -subunits, using as marker native α -bungarotoxin (α -BTX, M_r 8,000; ref. 3). We report here the results obtained at 20 Å resolution by electron microscopy and single-particle image averaging⁴, which reveal two well-defined regions within the AChR structure^{5,6} where the mass increases significantly on binding of α -BTX. One of these (α_1) is adjacent to the region where the δ -subunit has been located⁶; the second region (α_2) is diametrically across the molecule, ~50 Å away from the δ -subunit and also from (α_1). The topography revealed by direct structural analysis can explain the results of previous nearest-neighbour cross-linking studies^{2,7}.

AChR-rich membrane fragments isolated from *Torpedo marmorata* electric organ had a specific activity of 1.9 nmol ³H-labelled α -BTX per mg protein. Aliquots (5 μ l; 7 mg protein per ml) were incubated for 60 min with 45 μ l of H₂O which had been adjusted to pH 11 by NaOH, then 120 μ l of H₂O were added and the aliquots were centrifuged in a Beckman Airfuge at 20 p.s.i. for 2 min. The pellets were resuspended and incubated for 90 min in 30 μ l of buffer (100 mM NaCl, 10 mM Na-phosphate pH 7.4, 1 mM EDTA) with α -BTX [30 μ g ml⁻¹; (+)] or without (-). Buffer was then added to 175 μ l and the samples were centrifuged as before. The final pellets were each resuspended in 20 μ l of H₂O. For the (+) sample (pre-incubated with α -BTX) no binding of ³H-labelled α -BTX was detected, indicating saturation of the available binding sites, whereas the value for the (-) sample was 1.4 nmol

per mg protein. Negatively-stained electron microscope specimens were prepared in parallel, with the same batch of carbon film as reported elsewhere^{5,8}.

Figure 1a,b shows average images of membrane-bound AChR. They were obtained after alignment of individual images of negatively-stained specimens of AChR-rich membrane fragments (microsacs), from which non-receptor peptides had been removed by alkaline washing⁹. These microsacs had been incubated either with [Fig. 1a, (+)] or without [Fig. 1b, (-)] α -BTX. Figure 1a,b represents average axial projections (perpendicular to the membrane plane) of the stain-excluding mass in mem-

brane bound AChR. Their difference map [$\Delta = (+) - (-)$; Fig. 1c] shows two statistically significant peaks within the stain-excluding region of the particle. Given that only about half of the mass of each AChR molecule contributes to the stain exclusion⁶, we may roughly estimate from the size of the difference peaks that the mass added to either of the two regions on binding of α -BTX amounts to less than about one-quarter of the mass of an α -subunit (M_r 40,000).

Extensive tests were done to assess the reliability of the results. As the optical density \bar{d}_{ik} in any image element (ik ; $i, k = 1, \dots, m$; $m = 32$) of an average image is the mean

Fig. 1 Average images from negatively stained, membrane-bound AChR particles: *a*, obtained after incubation with α -BTX (+). *b*, Control [without α -BTX, (-)]. *c*, Difference [$\Delta = (+) - (-)$]. Optical density (OD) is low in bright and high in dark regions: thus, the stain-excluding mass appears bright. The density maximum of both *a* and *b* (in OD units) is 1.36. The grey levels in *a*, *b* and *c* are spaced at intervals of 0.029 OD units. Width of each map; 128 Å. *a*, *b* and *c* were low-pass-filtered to a resolution of 18 Å. For technical reasons related to image rotations and translations during alignment, only the central regions (~100 Å in diameter), but not the corners of the maps should be interpreted. The averages show the typical horseshoe-shape of the axial projections of negatively stained membrane-bound AChR particles^{5,6,21-23}. There are two regions where the stain-excluding mass increases on binding of α -BTX (*a*). This is clearly revealed by the difference map (*c*) which possesses two distinct negative peaks (-0.08 OD units) within the particle outline. The grey level closest to zero is marked by an asterisk. *d*, An unfiltered map of the standard error of the difference (s_{ik}^2 , see text) using eight grey levels spaced at intervals of one-tenth of those in *a-c*. (Low values dark, high values bright, minimum 0.017, maximum 0.031.) The lowest errors occur within the region of the stain-excluding mass of the AChR particle. Computer processing (using the SPIDER software system²⁴) of digitized micrographs taken with a scanning transmission electron microscope (STEM) was as follows^{5,6}: a large field of view was segmented into small areas, each containing a single AChR particle. A circular mask (64 Å diameter) was used to screen off the surroundings of the particles^{5,6}. The rotation angles and translation vectors relative to a reference particle were determined by correlation functions, and the individual particles aligned and averaged. Each data set [(+) and (-)] comprised 40 particles. A particle chosen at random from the (+) set was used as a common reference for both data sets. In a second cycle (refinement) each set was aligned again, its previously obtained average now acting as the reference. The masked-off regions were aligned passively and included in the final average. For imaging in the STEM the elastically scattered electrons were used ('incoherent darkfield imaging'). With this type of instrument the image recording conditions (magnification, focus, minimized electron irradiation, optical density) are the same for each set of micrographs. Moreover, images were recorded within a few hours on the same strip of film, making scaling to compensate for instrumental variations unnecessary; that is, (for symbols see text) if the scaling procedure is described by $\bar{d}_{ik}^* = a\bar{d}_{ik} + b$, then $a = 1.0$, $b = 0$. This was confirmed by measurements of the optical density on unstained parts of the carbon films. There remained the possibility that either the two preparations were not equally embedded in negative stain or the stain was not equally dense. The respective optical density characteristics (maximum, minimum, mean, s.d.), as averaged over each of the two sets of micrographs, differed by ~20%. Assuming that this did not indicate structural differences, but unequal staining, the characteristics could be closely matched by setting $a = 1.2$. Thus, it became necessary to establish the effect that scaling might have had on the difference maps. (No scaling was applied to the data shown here.) If the mean density $\bar{\Delta}$ of the difference map is given by

$$\bar{\Delta} = (1/m^2) \sum_{i,k} \Delta_{ik}^- \quad (\text{see text also})$$

and the image variance s_{Δ}^2 of the difference image by

$$s_{\Delta}^2 = \frac{\sum_{i,k} (\bar{\Delta} - \Delta_{ik}^-)^2}{m^2(m^2 - 1)}$$

we may take s_{Δ}^2 as a measure of the total amount of contrast variation (power) in the difference image. The effect of scaling on s_{Δ}^2 was investigated by varying a ($0.5 \leq a \leq 2.0$) in increments of 0.1. This indicated that the overall difference between the (+) and (-) averages within the stain-excluding region (surroundings screened off) can be minimized by setting $a = 1.3$. Nevertheless, for $0.8 \leq a \leq 1.5$, the height of the difference peaks (*c*) exceeded three times the standard error, s_{ik}^2 , of the difference ($3s_{ik}$ -criterion; see *d* and text). On increasing a from 1.0 to 1.5 the difference peak at the lower left (designated α_1 in Fig. 3) moved radially by 10 Å from its position within the main stain-excluding region to a more peripheral position. The position of the other peak (α_2 in Fig. 3) was insensitive to scaling. No additional peaks emerged. These tests show that by applying physically reasonable scaling factors, the difference peaks cannot be made to disappear below the noise level and that the difference indeed indicates a net total increase in stain-excluding matter in the (+)-image relative to the (-)-image. The effect of optical density scaling was also investigated using the phase residual (see Fig. 2) as a criterion. The results were in full agreement with those discussed above. The difference maps *e-h* were obtained in the same manner (including the investigation of scaling effects) as described for *c* and are presented using the same density increment (0.029 OD units). Again, the asterisks mark the levels closest to zero; *e* and *f* are formed between the (+)-average and averages from untreated (O) or disulphide-reduced (R; using 10 mM dithiothreitol¹⁶) membrane fragments, respectively. Thus, *e* corresponds to (+)-(O) and *f* to (+)-(R). The density minima of *e* and *f* within the stain-excluding region are -0.085 and -0.11 OD units, respectively. The reproducibility of the averages may be assessed from the difference maps *g* and *h* which correspond to (-)-(-) and (-)-(R), respectively. Within the stain-excluding regions *g* and *h* show variations of $< \pm 0.03$ OD units, which are not significant according to the $3s_{ik}$ -criterion applied throughout this work. In all difference maps, the peaks occurring in the stain regions would have to exceed ~0.1 OD units to be considered statistically significant. Note that the projection maps of the receptor particles differ from those presented earlier⁵. This is due not only to the application of a refinement cycle, but also to the inclusion of all particles in the course of the so-called '180°-decision'⁵. This applies to all data used here and is an improvement on our previous procedure, done in response to criticism raised by A. Brisson²¹, who independently confirmed the structure of the stain-excluding region by a different single-particle alignment method.

of N realizations d_{ik}^n ($n = 1, \dots, N; N = 40$)

$$\bar{d}_{ik} = (1/N) \sum_{n=1}^N d_{ik}^n$$

the standard error of the mean

$$s_{ik} = \sqrt{\frac{\sum_n (d_{ik}^n - \bar{d}_{ik})^2}{N(N-1)}}$$

was used as a criterion for assessing the significance of the difference $\Delta_{ik}^+ = \bar{d}_{ik}^+ - \bar{d}_{ik}^-$ (Fig. 1a,b) between corresponding image elements in the averages of the two sets. This difference was considered significant if it exceeded three times the standard errors (s_{ik}^+, s_{ik}^-) of the (+)– and (–)–averages. A map of the standard error of the difference

$$s_{ik}^{\Delta} = \sqrt{(s_{ik}^+)^2 + (s_{ik}^-)^2}$$

is shown in Fig. 1d. To apply this criterion we must assume that the values of d_{ik}^n have a gaussian distribution, and that the images are aligned correctly (see Fig. 1 legend). The hypothesis that the d_{ik}^n are normally distributed could not be rejected (Kolmogorov–Smirnov test¹⁰). The reliability of the alignment procedure can be deduced from a comparison of independent averages, using the phase residual as a measure of the reproducible resolution¹¹ (Fig. 2). Additionally, a non-crystallographic test¹² was developed on the basis of non-parametric statistical methods¹³ and applied to aligned and non-aligned image sets. This test requires neither gaussian distributions nor statistical independence of the data; for any image element of an average image and at any significance level it specifies a threshold to be exceeded by the contrast of nearby elements. This method established that after alignment, the density of the stain-excluding regions varied significantly (at the 95% confidence level) over distances of ~ 20 Å. When the images had been aligned merely by translation, omitting rotational alignment (so

Fig. 3 Schematic representation of the subunit topography of the membrane-bound AChR protein viewed in axial projection perpendicular to the membrane plane. The approximate positions of the α_1 -, α_2 - and δ -chains have been determined directly.

that only their stain-filled centres were in register), significant density variations were lacking in the diffuse annulus representing the average stain-excluding mass.

In the preparation of the specimens, we applied an alkaline washing step⁹ to improve the image contrast of the AChR particles⁸. It extracts non-receptor peptides without either affecting the function (α -BTX binding, ion fluxes) of the AChR^{8,14} or altering the lipid composition of the microsacs¹⁵. Extraction of non-receptor peptides does not affect the internal structure of the stain-excluding mass of membrane-bound AChR¹⁶. Changes occur only near the periphery of the particles (unpublished results); they differ from the effect of disulphide reduction which abolishes a pairwise association of nearest-neighbour particles⁶. Thus, difference maps may also be formed between the average shown in Fig. 1a and averages from untreated microsacs (O) or from microsacs after disulphide reduction (R). These maps ((+)–(O); Fig. 1e, and (+)–(R); Fig. 1f) show essentially the same features as (+)–(–) (Fig. 1c); phase residuals between these maps were consistently smaller than 45° for spatial frequencies $< 1/18$ Å^{–1}. Accordingly, difference maps between the averages without α -BTX in various combinations, for example, between (–) and a corresponding average (–') from an independent data set [(–)–(–')] (Fig. 1g; see also Fig. 2) or (–)–(R) (Fig. 1h)] lacked significant peaks within the stain-excluding region.

We therefore believe that the two difference peaks in Fig. 1c are not only statistically significant, but indeed are due to bound α -BTX marking the α -subunits (α_1, α_2 ; Fig. 3). A substantial exclusion of stain by the toxin might be expected because the 'long toxins' are known to have a rather compact structure stabilized by five disulphide bridges^{3,17}. Furthermore, a compact AChR–toxin complex is suggested by the extensive surface contacts between toxin and AChR (~ 200 van der Waals contacts have been estimated¹⁸). Nevertheless, the unequal sharpness of the two difference peaks indicates that the precision of the localization is not the same for α_1 and α_2 .

Although this study provides no clues as to the location of the putative ACh-activated ion channel, it excludes the possibility that α -BTX acts by physically blocking the entrance to the central cavity of the hydrated mass in the membrane-bound AChR. From the available three-dimensional data^{6,16}, we estimate that this cavity—visualized by the densely stained pit—could accommodate a protein mass of $M_r \sim 10,000$. α -BTX (M_r 8,000) bound to this region would have been clearly revealed.

In Fig. 3 we have also indicated the previously obtained position of the δ -subunit as defined by the contact region between adjacent AChR monomers that are disulphide-linked between their respective δ -subunits⁶. As the δ – δ bond is well documented², the δ -subunit is a convenient reference point for establishing the relative topography of other subunits. The positions of $\beta?$ and $\gamma?$ in Fig. 3 are based merely on the following circumstantial evidence. Extraction of non-receptor peptides (mainly of the M_r 43,000 component (ν)⁹ by alkaline

Fig. 2 Differential plots of the phase residual¹¹

$$\Delta\theta = \sqrt{\frac{(|F_1| + |F_2|)\Delta\delta^2}{(|F_1| + |F_2|)}}$$

where F_1 and F_2 denote corresponding complex Fourier coefficients of two (independent) average images and $\Delta\delta$ is their phase difference. The summations extend over a ring zone $S_1 \pm \Delta S$ of the reciprocal space. This analysis shows that $\Delta\theta$ is less than 45° when independent averages (○) taken over >20 aligned images are compared, and that presentation at 18 Å resolution is justified. The plots also illustrate the improvement achieved on alignment by comparing two arbitrarily chosen single particles before (×) and after (□) alignment. In this analysis, which was aimed at demonstrating the reproducible resolution in the stain-excluding mass of the AChR particles, a circular mask (64 Å diameter) was used to screen off the particle surroundings.

washing uncovers antigenic determinants on α , γ and δ (ref. 14). Depletion of skin-excluding mass on alkaline washing was observed (unpublished results) in the neighbourhood of the AChR, near α_2 and δ . This led to the tentative assignment of γ ? to the area between α_2 and δ (Fig. 3).

Thus, we conclude that one of the two α -chains (α_1) is situated in the immediate vicinity of a δ -chain, and that α_2 is ~ 50 Å away. Biochemical labelling and cross-linking studies (reviewed by Karlin² and Hucho⁷) have shown that all chains of the AChR are in close proximity. Despite considerable difficulties in their interpretation, such experiments provide evidence that α and δ are the species most readily cross-linked to one another, whereas cross-links between the two α -chains have not been found. Our result, while in broad agreement with these conclusions, helps to resolve the fundamental difficulty that cross-

linking experiments give equivocal results if they cannot distinguish between the two copies of the α -chain. In membrane-bound AChR the two recognition sites, one on each α -chain, are indistinguishable in their ability to bind snake α -toxins, and in the kinetics of this binding¹⁹. On the other hand, differences seem to exist with respect to affinity labelling^{2,20}. A further difference is directly manifested in the environment of each α -chain (Fig. 3): each toxin-binding region exhibits contacts with a different set of neighbouring subunits, reinforcing the evidence for the asymmetric quaternary structure of the AChR-protein.

The linear Onsager coefficients for biochemical kinetic diagrams as equilibrium one-way cycle fluxes

Terrell L. Hill

Laboratory of Molecular Biology, National Institute of Arthritis, Diabetes, and Digestive and Kidney Diseases, National Institutes of Health, Bethesda, Maryland 20205, USA

In a biochemical kinetic diagram¹, the various discrete states of an enzyme or enzyme complex are represented by points, and interstate transitions are represented by lines. Figure 1 is an example. I show here that, for steady states near equilibrium, the phenomenological Onsager coefficients in the linear flux-force equations that are a consequence of any such diagram have a transparent physical interpretation: these coefficients are simple combinations of one-way cycle fluxes¹ at equilibrium. The existence of this kind of relationship was pointed out recently in an appendix of a paper² on another subject. I present here the explicit connection between the phenomenological coefficients and the one-way cycle fluxes of the diagram. These coefficients are considered by many scientists to be strictly empirical and incomprehensible. My report provides a simple interpretation of them, at the molecular level, for any biochemical kinetic diagram. This is analogous to the molecular interpretation of phenomenological equilibrium thermodynamics that is provided by statistical mechanics.

Instead of treating a completely arbitrary diagram with generalized notation, the general rule can easily be deduced from a special case that has sufficient complexity. For this purpose we use the hypothetical model of the (Na⁺ + K⁺)ATPase complex shown in Fig. 1. First, cycles and one-way cycle fluxes are introduced for this model, and then their relationship to the Onsager linear coefficients is pointed out.

The hypothetical diagram (or reaction mechanism) in Fig. 1a has eight enzyme states and six cycles. The latter are shown in Fig. 1b. The anticlockwise direction is chosen as positive. The

dominant cycle is 'g'. The enzyme complex is in a membrane separating 'in' and 'out'. For each completed g cycle, in the + direction, two K⁺ ions are transported out \rightarrow in, three Na⁺ ions are transported in \rightarrow out and one ATP molecule is hydrolysed. The transitions 2 \rightleftharpoons 7 and 3 \rightleftharpoons 6 introduce some slippage and also introduce the other five cycles included in Fig. 1b: cycle a (+ direction) transports two K⁺ out \rightarrow in, cycle d (+ direction) transports two K⁺ out \rightarrow in and three Na⁺ in \rightarrow out, and so on.

The observable steady-state fluxes, per complex, are denoted J_K , J_N and J_T , for K⁺, Na⁺ and ATP, respectively. These are all chosen as positive in the normal operating directions specified above. The corresponding thermodynamic forces, per ion or molecule, are then $X_K(\text{out} \rightarrow \text{in})$, $X_N(\text{in} \rightarrow \text{out})$ and X_T , where X_K and X_N are negative, and X_T is positive. In normal operation, K⁺ and Na⁺ are driven across the membrane against their thermodynamic forces by the dominant force X_T .

There are 10 lines in the diagram and hence 20 first-order (or pseudo-first-order) rate constants (units, say, s⁻¹). If these rate constants are all specified, the three observable steady-state fluxes can be written as sums of separate cycle contributions¹:

$$\begin{aligned} J_K &= 2(J_a + J_d + J_g) \\ J_N &= 3(J_b + J_d + J_f + J_g) \\ J_T &= J_c + J_f + J_g \end{aligned} \quad (1)$$

All these fluxes are in units of s⁻¹ per complex. J_a is the net mean rate of cycle a completions in the + direction, and so on. Cycles a, d and g appear in the J_K equation because (see Fig. 1) these and only these three cycles are involved in K⁺ transport (two K⁺ per cycle). Each cycle flux J_κ ($\kappa = a, \dots, g$) above can be expressed in terms of the first-order rate constants of the diagram in the form¹

$$J_\kappa = (\Pi_\kappa^+ - \Pi_\kappa^-)F_\kappa \quad (2)$$

where Π_κ^+ is the product of rate constants around cycle κ in the positive direction, Π_κ^- is the same for the negative direction and F_κ is a positive algebraic combination of all 20 rate constants of the diagram (the details¹ of which are not needed here).

Actually, κ cycles can be completed in either direction, and J_κ can be decomposed as follows¹:

$$J_\kappa = J_{\kappa^+} - J_{\kappa^-}, \quad J_{\kappa^+} = \Pi_{\kappa^+} F_{\kappa^+}, \quad J_{\kappa^-} = \Pi_{\kappa^-} F_{\kappa^-}, \quad (3)$$

where J_{κ^+} is the mean rate (s^{-1}) at which κ cycles are completed in the + direction at steady state, and similarly for J_{κ^-} . The fluxes J_{κ^+} and J_{κ^-} are the one-way cycle fluxes for cycle κ . Both J_{κ^+} and J_{κ^-} are positive but J_κ might be negative. Separate cycle fluxes or separate one-way cycle fluxes are generally not directly observable. If a tracer were used in our example, one could observe, say, the sum

$$J_{\kappa^+} = 2(J_{a^+} + J_{d^+} + J_{g^+}) \quad (4)$$

but not J_{a^+} , J_{d^+} and J_{g^+} separately. However, as will be seen below, it is possible in some cases to determine, experimentally, equilibrium values of one-way cycle fluxes. Returning to equation (3), we note that

$$J_{\kappa^+}/J_{\kappa^-} = \Pi_{\kappa^+}/\Pi_{\kappa^-} \quad (5)$$

in which F_{κ} does not appear.

The thermodynamic force X_κ , operating in cycle κ , is determined by the processes included in cycle κ :

$$X_a = 2X_K, \quad X_b = 3X_N, \quad X_c = X_T, \quad X_d = 2X_K + 3X_N \quad (6)$$

$$X_f = 3X_N + X_T, \quad X_g = 2X_K + 3X_N + X_T$$

Each cycle force X_κ is simply related¹ to Π_{κ^+} and Π_{κ^-} for the cycle:

$$\Pi_{\kappa^+}/\Pi_{\kappa^-} = e^{X_\kappa/kT} = J_{\kappa^+}/J_{\kappa^-} \quad (7)$$

where the last relation makes use of equation (5).

The above discussion applies to an arbitrary steady state. Here, steady states near equilibrium are considered. For this we require

$$|X_K|/kT, \quad |X_N|/kT, \quad |X_T|/kT \ll 1 \quad (8)$$

However, if only cycle g is important, the near-equilibrium condition is much less stringent:

$$|X_g|/kT = |2X_K + 3X_N + X_T|/kT \ll 1 \quad (9)$$

Only the sum need be small, not the separate forces. This important special case will be referred to again below.

Returning to the general case, equation (8), remember that the model in Fig. 1 is being used here simply as a sufficiently complicated example from which to see general results. The conditions in equation (8), especially $|X_T|/kT \ll 1$, are certainly not important for the real $(Na^+ + K^+)$ ATPase (see below in this connection). Near equilibrium, the phenomenological flux-force relations are, as is well known,

$$J_K = L_{KK}X_K + L_{KN}X_N + L_{KT}X_T$$

$$J_N = L_{NK}X_K + L_{NN}X_N + L_{NT}X_T \quad (10)$$

$$J_T = L_{TK}X_K + L_{TN}X_N + L_{TT}X_T$$

where, as Onsager showed for a wide class of systems, the matrix L_{ij} is symmetric (that is, $L_{ij} = L_{ji}$). Our object is to relate the L_{ij} for a biochemical kinetic diagram to the one-way cycle fluxes. In doing this, the symmetry of the matrix will appear automatically.

At an arbitrary steady state, the rate of free energy dissipation is

$$TdS/dt = J_KX_K + J_NX_N + J_TX_T \geq 0 \quad (11)$$

Here X_K and X_N are negative and the other four factors are positive. Near equilibrium, using equations (10) and $L_{ij} = L_{ji}$,

$$TdS/dt = L_{KK}X_K^2 + L_{NN}X_N^2 + L_{TT}X_T^2 + 2L_{KN}X_KX_N$$

$$+ 2L_{KT}X_KX_T + 2L_{NT}X_NX_T \geq 0 \quad (12)$$

This is a non-diagonal quadratic form in which the last two terms are usually negative.

We turn now to a consideration of cycles. In view of equations (6) and (8), all of the $|X_\kappa|/kT \ll 1$. From equations (3) and (7),

Fig. 1 Hypothetical model of $(Na^+ + K^+)$ ATPase in a membrane, in the form of a biochemical kinetic diagram (a). The enzyme complex has eight significant states, which need not be specified explicitly. The diagram has six cycles (b). All fluxes are chosen as positive in the anticlockwise direction.

we have then

$$J_\kappa = J_{\kappa^+} - J_{\kappa^-} = J_{\kappa^+}[(J_{\kappa^+}/J_{\kappa^-}) - 1]$$

$$= J_{\kappa^+}(e^{X_\kappa/kT} - 1) = J_{\kappa^+}(X_\kappa/kT) + \dots \quad (13)$$

The last form is the near-equilibrium special case. At equilibrium, the two one-way cycle fluxes for cycle κ are equal to each other, because $J_\kappa = 0$. That is, $J_{\kappa^+} = J_{\kappa^-}$. We denote either of these by $J_{\kappa^+}^e$ [as in equation (13)]. $J_{\kappa^+}^e$ is a positive quantity; it is the one-way cycle flux, at equilibrium. $J_{\kappa^+}^e$ can be expressed¹ in terms of the rate constant set of the diagram at equilibrium, using equation (3), but the physical interpretation of $J_{\kappa^+}^e$, just mentioned, is the main point of interest here.

If we now substitute the last form of equation (13), for cycles a, d and g, into the J_K equation in equations (1), and then use equations (6) to eliminate X_a , X_d and X_g , we obtain

$$J_K = 2 \left[J_{a^+}^e \left(\frac{2X_K}{kT} \right) + J_{d^+}^e \left(\frac{2X_K}{kT} + \frac{3X_N}{kT} \right) \right.$$

$$\left. + J_{g^+}^e \left(\frac{2X_K}{kT} + \frac{3X_N}{kT} + \frac{X_T}{kT} \right) \right]$$

$$= 4(J_{a^+}^e + J_{d^+}^e + J_{g^+}^e)(X_K/kT)$$

$$+ 6(J_{d^+}^e + J_{g^+}^e)(X_N/kT) + 2J_{g^+}^e(X_T/kT) \quad (14)$$

If we follow the same procedure for J_N and J_T , and then compare with equations (10), we find for the L_{ij} :

$$L_{KK} = 4(J_{a^+}^e + J_{d^+}^e + J_{g^+}^e)/kT$$

$$L_{NN} = 9(J_{b^+}^e + J_{d^+}^e + J_{f^+}^e + J_{g^+}^e)/kT$$

$$L_{TT} = 1(J_{c^+}^e + J_{f^+}^e + J_{g^+}^e)/kT \quad (15)$$

$$L_{KN} = L_{NK} = 6(J_{d^+}^e + J_{g^+}^e)/kT$$

$$L_{KT} = L_{TK} = 2J_{g^+}^e/kT$$

$$L_{NT} = L_{TN} = 3(J_{f^+}^e + J_{g^+}^e)/kT$$

The symmetry of the matrix appears at this point. The rules for the construction of equations (15), merely by inspection of the diagram and cycles, are obvious from the first form of equation (14): (1) those cycles that include process i contribute to L_{ii} ; (2) those cycles that include both process i and process j contribute to L_{ij} (hence the matrix is symmetrical); (3) the integral numerical coefficients in the L_{ij} are determined by a matrix of stoichiometric products. In the present example, the product matrix is (order K, N, T).

$$\begin{pmatrix} 2.2 & 2.3 & 2.1 \\ 3.2 & 3.3 & 3.1 \\ 1.2 & 1.3 & 1.1 \end{pmatrix} \quad (16)$$

From the simple construction of the first form of equation (14), it is clear that the above rules apply to any diagram. Thus there is a simple physical interpretation of the L_{ij} matrix for any diagram in terms of the equilibrium one-way cycle fluxes of the cycles of the diagram.

The signs of the L_{ij} ($i \neq j$) need not always be positive, as in this example. Thus, suppose we reverse the signs of J_K and X_K in equations (1) and (6) (this is a matter of convention), then we find that a minus sign appears in the expressions for $L_{KN} = L_{NK}$ and for $L_{KT} = L_{TK}$ in equations (15). This was, in fact, the choice made in ref. 1, equation (3.66). However, negative signs can be avoided by choosing all fluxes (operational and cycle) as positive in the same direction.

In principle, the L_{ij} can all be measured by observing the operational steady-state fluxes and forces in equations (10), near equilibrium. With these available, all of the J_K^* can be deduced from equations (15), in the order, for example, g, d, f, a, c, b. Thus, the equilibrium one-way cycle fluxes can be obtained from conventional flux-force measurements. This will be possible, in principle, whenever the number of cycles (with non-zero force and flux¹) in the diagram does not exceed $n(n+1)/2$ (the number of independent L_{ij}), where n is the number of operational fluxes (or forces) in the system.

If only cycle g contributes to the fluxes, we have, near equilibrium

$$J_K = 2J_g^* (X_g/kT), \quad J_N = 3J_g^* (X_g/kT), \quad J_T = J_g^* (X_g/kT) \quad (17)$$

where X_g is given in equation (6). Each linear coefficient is determined by the equilibrium one-way cycle flux of the only operative cycle and by the stoichiometry of that cycle. Here we have integral 2:3:1 stoichiometry between the observable fluxes. If other cycles participate, this exact stoichiometry will be lost.

If we substitute equations (1) into equation (11), and then use equations (6), the rate of free energy dissipation at an arbitrary steady state can be expressed in terms of cycle contributions rather than of observable process contributions:

$$Td_iS/dt = J_a X_a + J_b X_b + J_c X_c + J_d X_d + J_f X_f + J_g X_g \geq 0 \quad (18)$$

Whereas $J_K X_K$ and $J_N X_N$ in equation (11) are negative, no term in equation (18) can be negative. This follows from equations (2) and (7): J_K and X_K have the same sign. Near equilibrium, we put the last form of equation (13) into equation (18), in place of each J_K , and obtain

$$(1/k)d_iS/dt = J_a^* (X_a/kT)^2 + \dots + J_g^* (X_g/kT)^2 \geq 0 \quad (19)$$

Unlike equation (12), this is a diagonalized quadratic form, with every term positive.

Equations (18) and (19), for cycles, have the same mathematical properties as when the individual molecular transitions of a diagram are used (see, for example, equation (4.28) of ref. 1). That is, if we advance, conceptually, from the molecular level to the cycle level these properties are still retained, though they are lost if we go still further to the observable process level, as mentioned following equations (11) and (12). Thus, although cycles are composites of many molecular transitions, in some thermokinetic respects they still resemble individual transitions (for further discussion, see ref. 1).

Although the analogy to the present cycles is not close, it is interesting that Haase³ has shown that the L_{ij} for an arbitrary set of coupled homogeneous chemical reactions can be expressed in terms of one-way reaction fluxes at equilibrium.

We are here primarily concerned with the general question of the relationship between the L_{ij} and cycles for an arbitrary diagram, near equilibrium. Essentially as an addendum we note that, as is well known, many free energy transducing systems in membranes seem to be dominated by a single cycle (for example, cycle g in Fig. 1b) that operates rather near to equilibrium; other slippage cycles are probably used to a limited extent but the forces in these cycles are very far from equilibrium. Thus, if more than one (the main) cycle is used, the above uniformly-near-equilibrium treatment does not apply.

The model in Fig. 1 for $(Na^+ + K^+)ATPase$ can be used as an illustration. In normal operation, X_K and X_N are large and negative, X_T is large and positive, but $X_g = 2X_K + 3X_N + X_T$ is small and positive (cycle g is near equilibrium). Consequently,

from equations (6),

$$X_a, J_a; X_b, J_b; X_d, J_d \text{ are negative} \\ X_c, J_c; X_f, J_f \text{ are positive} \quad (20)$$

The forces in expression (20) are all large in magnitude but the fluxes are relatively small because the slippage rate constants ($2 \rightleftharpoons 7$, $3 \rightleftharpoons 6$) are relatively small. Furthermore, these cycle fluxes will be essentially one-way cycle fluxes, because of the large cycle forces [equation (7)]. Because X_g is positive, J_g is positive. Equations (1), in this case, become

$$J_K = 2[-J_a - J_d + J_g^* (X_g/kT)] \\ J_N = 3[-J_b - J_d + J_f + J_g^* (X_g/kT)] \\ J_T = J_c + J_f + J_g^* (X_g/kT) \quad (21)$$

The one-way cycle fluxes J_a^*, \dots, J_f^* that appear here are not equilibrium fluxes. The corresponding cycle forces do not enter these equations because, for these cycles, the activity is almost one-way (irreversible). The cycle g terms usually dominate; the other terms are slippage corrections which, incidentally, would spoil the exact 2:3:1 stoichiometry of cycle g. All the terms in equations (21) can be expressed¹ as functions of the rate constants of the diagram at this steady state.

I thank Dr S. R. Caplan for significant suggestions and corrections.

ATP-dependent unwinding of double helix in closed circular DNA by RecA protein of *E. coli*

Takuzo Ohtani*, Takehiko Shibata†, Masa-aki Iwabuchi, Hiro-omi Watabe, Tohru Iino & Tadahiko Ando

Department of Microbiology, Riken Institute (Institute of Physical and Chemical Research), Wako-shi, Saitama, 351, Japan

RecA protein is an essential component directly involved in general genetic recombination in *Escherichia coli*^{1,2}. In the presence of ATP, RecA protein promotes *in vitro* pairing of homologous DNA molecules^{3–9}, unidirectional elongation of heteroduplex joints^{7,10–12} and concerted reciprocal strand exchange^{13,14}. These activities of the protein can explain some important steps in genetic recombination (see ref. 15 for review). When negative-superhelical closed-circular double-stranded DNA (form I DNA) is a substrate, RecA protein catalyses a cycle of sequential reactions: formation and dissociation of D-loops, and inactivation and reactivation of the duplex as a substrate for D-loop formation^{16,55}. We now present evidence that, in the presence of ATP, RecA protein unwinds the double helix of form I DNA to produce positive-superhelical turns which can be relaxed by eukaryotic topoisomerase I and that, by this process, closed-circular double-stranded DNA with an extraordinarily large number of negative-superhelical turns can be formed in physiological conditions. This ATP-dependent unwinding of the double-helix might promote dissociation of D-loops in form I DNA, followed by inactivation of the form I DNA and the elongation of heteroduplex joints, as suggested by our previous studies^{16,17,55}.

* Present address: Hamari Chemicals Ltd., Higashi-Yodogawa-ku, Osaka-shi, 553, Japan.
† To whom correspondence should be addressed.

The superhelicity of DNA is thought to play a part in genetic recombination^{15,18-22}. When form I DNA was incubated with homologous single-stranded fragments, excess ATP and excess RecA protein at 37°C, D-loops were formed in the early stage of the incubation and then completely dissociated^{16,17,55} (Fig. 2a). When D-loops are completely dissociated, all form I DNA becomes an inactive substrate for D-loop formation¹⁶. These latter two processes can be explained by a model in which free RecA protein (RecA protein that does not bind to single-stranded DNA) binds to double-stranded DNA cooperatively from the site of the D-loop and unwinds the double helix unidirectionally. Unidirectional unwinding of the double helix in form I DNA in the absence of any topoisomerase activity^{23,24} results in relaxation of negative supercoiling and then the accumulation of positive supercoiling, followed by rewinding of the double helix at the trailing end of the unwound region to relax the positive supercoiling (illustrated in Fig. 1, steps from (i) to (iii) via (ii)).^{16,17,55}

To obtain direct evidence for unwinding of the double-helix in form I DNA in an inactivated state, we performed the following experiments. After the formation and subsequent complete dissociation of the D-loops by incubation of form I ³H-labelled DNA with homologous single-stranded fragments, ATP and RecA protein for 50 min (the first incubation), we treated the form I DNA for 5 min at 37°C with an eukaryotic topoisomerase I prepared from *Saccharomyces cerevisiae* (the second incubation). Eukaryotic topoisomerase I, including that from *S. cerevisiae*, is able to relax both positive and negative supercoiling (see refs 25, 26 for review, also H.W. and T.I., unpublished observation). When both the first incubation and RecA protein in the second incubation were omitted, the duplex DNA was completely converted to relaxed form (form IV) by the second incubation and exhibited a set of closely spaced bands near a band produced by nicked-circular DNA (form II

Fig. 1 Schematic diagram of the experiments to demonstrate unwinding of the double helix by RecA protein. Basically, when we compare the average linking numbers between a closed-circular DNA relaxed by topoisomerase in the presence of double helix unwinding reagents (iv) or (vii), and that relaxed in their absence, the difference directly indicates the angle of unwinding by the reagents⁴⁹⁻⁵¹. The double helix is unidirectionally unwound by RecA protein (indicated by small arrows) in (ii), (iii) and (iv). Unidirectional unwinding by RecA protein is initiated very efficiently at the site of a D-loop (small arrow in (ii)). In the case of negative-superhelical DNA (form I DNA), the initiation occurs at a very low rate even in the absence of any single-stranded DNA (indicated by broken line from (i) to (iii)), probably at transient denatured sites. Because, in the absence of topoisomerase activity, the unidirectional unwinding of the double-helix in closed-circular DNA results in the loss of negative supercoiling of form I DNA, dissociation of D-loops (steps from (ii) to (iii)) and then positive supercoiling of the form I DNA (iii). The product is then treated with eukaryotic topoisomerase I in the presence of active RecA protein (indicated by A + T). The positive supercoiling of the form I DNA (iii) is relaxed and the unwound region extended (iv). After proteins are removed (step indicated by d), product (iv) becomes a form (vii) with a larger number of negative-superhelical turns than natural form I DNA (v). When the double helix is not unwound, negative supercoiling of form I DNA is relaxed with topoisomerase I. A, T and ss denote RecA protein, topoisomerase I and homologous single-stranded fragments, respectively.

Fig. 2 Formation and dissociation of D-loops, and formation of form X. fd form I ³H DNA preparation (4 μ M, containing 75% form I DNA) and 0.05 μ M homologous single-stranded fragments were incubated with 1 μ M (in a, open symbols, and in b) or 0.5 μ M (in a, closed symbols) RecA protein (molecular weight 40,000) and 1.3 mM ATP in a reaction mixture (20.5 μ l) containing 31 mM Tris-HCl (pH 7.5), 13 mM MgCl₂, 1.8 mM dithiothreitol and 88 μ g of bovine serum albumin per ml at 37°C (the first incubation). RecA protein is a DEAE-cellulose fraction (fraction V) prepared as described previously²⁴. Preparation of DNA is described elsewhere²⁴. Amounts of DNA are expressed in moles of nucleotide residues. a, Samples were withdrawn at the indicated times and D-loops were assayed by the nitrocellulose-filter method^{16,33}. \circ , \bullet , Complete reaction mixture; \diamond , \blacklozenge , with heterologous (Φ X174) fragments; \triangle , \blacktriangle , without RecA protein. b, After treatment of fd form I DNA by the first incubation of 50 min, topoisomerase I from *S. cerevisiae*⁵² (30 μ g ml⁻¹) was added to the reaction mixture, followed by incubation for 5 min at 37°C. Reactions were terminated by chilling in an ice-water bath and by denaturing proteins with 0.5% Sarkosyl NL97 (Ciba-Geigy) and 4 μ l of phenol saturated with the buffer. Samples were then electrophoresed through 1% agarose gel in E-buffer⁵³ in the absence of dye at 20 V for 15 h at room temperature. After electrophoresis, the agarose gel (shown in Fig. 3) containing each lane was cut into several pieces, dissolved by boiling for 2-4 min with 0.1 M HCl, applied to a glass filter (Whatman GFC) and dried. Radioactivity on the filter was assayed in a Beckman LS8100 scintillation counter by using toluene scintillator. Percentage of radioactivity in bands formed by form I DNA and form X DNA to total recovered radioactivity is plotted. Topoisomerase I, with a molecular weight of 70,000 as estimated by gel filtration was purified ~8,000-fold by a series of chromatographies on an Ultrogel AcA 34 column, a double-stranded DNA-cellulose column and a hydroxylapatite column from the phosphocellulose fraction of *S. cerevisiae* IAM4274 prepared as described previously⁵⁴. This preparation of the topoisomerase is free of detectable endo- or exo-DNase, ATPase or DNA ligase activities and relaxes both positive and negative supercoiling by changing linking number in steps of one (H. W. and T.I., unpublished observation). 'ho' and 'he' indicate homologous single-stranded fragments and heterologous ones, respectively. RecA, ss frag and topo I indicate RecA protein, single-stranded fragments and the second incubation with topoisomerase I, respectively.

DNA) in the gel electrophoregram (Fig. 3, lane 9); about 99% of the recovered radioactivity of the input duplex DNA was in the bands of form IV and form II DNA. However, a large part of the duplex DNA from the complete reaction system formed a band which migrated significantly faster than the untreated form I DNA (Fig. 3, lane 14 compared with lanes 1 and 17). Here we tentatively call the form of DNA migrating faster than natural form I DNA form X, for simplicity.

We concluded from the following observations that form X is a closed-circular double-stranded DNA with an extraordinarily large number of negative-superhelical turns or much smaller linking number than natural form I DNA. Ethidium bromide is an intercalating dye which unwinds the double helix²⁷⁻²⁹. As shown in Fig. 4b, in the presence of 0.15 μ M ethidium bromide, untreated form I DNA behaved as the relaxed form in gel electrophoresis (lane 4), and form IV DNA as the positive-superhelical form (lanes 1-3). In this condition, form X DNA still behaved as a superhelical form (Fig. 4b, lanes 5-7). Form X DNA formed by the second incubation for 20 s could be relaxed by 0.7 μ M ethidium bromide in the gel (Fig. 4c, lane 5). In the presence of this concentration of the dye, both form I and form IV DNA behaved as the positive-superhelical form (Fig. 4c, lanes 1-4). The form X DNA formed by the second incubation for 5 min and that formed by the second incubation for 15 min were not relaxed by this concentration

Fig. 3 Gel electrophoresis of the product formed by RecA protein and topoisomerase I. Conditions for the reaction are given in Fig. 2 legend. As the length of single-stranded fragments used in this study was about 200 nucleotides, the fd form I DNA bearing a D-loop which was formed with these fragments was not relaxed (lane 4). The band produced by the single-stranded fragments was not significant in the conditions used here, because the single-stranded fragments migrated in a broad band and their concentration was only 1/70th of the duplex DNA. For lanes 1–8, the second incubation was omitted. The period of the first incubation was as indicated. For lanes 9–16, reaction mixtures were incubated with topoisomerase I for 5 min at 37°C after the indicated period of the first incubation. Lanes 1 and 9, without RecA protein for 0 min; lanes 2 and 10, complete reaction mixture for 0 min; lanes 3 and 11, with heterologous single-stranded fragments for 0 min; lanes 4 and 12, complete reaction mixture for 10 min; lanes 5 and 13, with heterologous single-stranded fragments for 10 min; lanes 6 and 14, complete reaction mixture for 50 min; lanes 7 and 15, with heterologous single-stranded fragments for 50 min; lanes 8 and 16, without single-stranded fragments for 50 min; lane 17, untreated form I DNA; lane 18, after 50 min of the first incubation of complete reaction mixture, 3 mM ADP was added to the reaction mixture and incubated for 30 min at 37°C. Then topoisomerase I was added and incubated for 5 min at 37°C. After electrophoresis, we photographed the gel as described previously²⁴.

of ethidium bromide (Fig. 4c, lanes 6, 7); the former was relaxed by the dye at 1–3 μ M and the latter by the dye at >5 μ M. These experiments also indicate that the extent of unwinding of the double helix in the closed-circular DNA gradually increases during the second incubation. A preliminary quantitative measurement of superhelicity using the ethidium bromide-buoyant density technique³⁰ showed that the form X formed

by the second incubation for 20 s has about twofold more superhelical turns than natural form I DNA (T.O. and T.S., unpublished result). This amount of supercoiling corresponds to the unwinding of about 800 base pairs (see ref. 24). As the velocity of unwinding of the double helix in form I DNA by RecA protein was calculated to be about one base pair per second¹⁶, the above experiments suggest that during the first incubation for 50 min, positive-superhelical turns seem to be accumulated in the duplex DNA (Fig. 1, product (iii)).

The amount of topoisomerase I added in these experiments completely relaxed form I DNA in the absence of RecA protein within 20 s (Fig. 4a, lane 1). After the first incubation for 50 min, 20 s of the second incubation was enough to convert almost all of the closed-circular DNA to form X (Fig. 4a, lane 5); 74% of the recovered radioactivity of the input duplex DNA which contained 77% form I DNA was in the band of form X in the gel electrophoregram in the absence of ethidium bromide (Fig. 4a, lane 5), and 92 and 8% of the radioactivity were in the bands of relaxed form and in the band of unreacted form I DNA, respectively, in the presence of 0.7 μ M ethidium bromide (Fig. 4c, lane 5).

The yield of form X DNA was the function of the period of the first incubation. When the first incubation was omitted, no form X was formed during the second incubation (Fig. 3, lane 10), and when the first incubation was not long enough to complete the dissociation of D-loops, a smaller portion of form I DNA was converted to form X (Fig. 3, compare lanes 12 and 14; see Fig. 2a). Therefore, the double helix of all form I DNA in an inactive state is extensively unwound and this unwinding correlates with the inactivation process, as suggested by the model described above.

The formation of form X required ATP (Fig. 2b), like the formation and dissociation of D-loops^{3,8,55}. Moreover, when ADP was added to the reaction system after the complete dissociation of D-loops and incubated, the duplex DNA was completely relaxed and no form X DNA was formed during the second incubation (Fig. 3, lane 18). This correlates with our previous observation that after the inactivation of form I DNA by formation and dissociation of D-loops, addition of ADP results in the full reactivation of the duplex⁵⁵.

On the other hand, formation of form X was greatly reduced when homologous single-stranded fragments were omitted or replaced by heterologous ones (Fig. 2b). Moreover, when we compared the initial velocity, the difference between the formation of form X in the presence of homologous single-stranded

Fig. 4 Effect of ethidium bromide on the migration of the products in gel electrophoresis. Conditions for the reaction and electrophoresis are given in Figs 2 and 3 legends. Samples were electrophoresed in the absence of ethidium bromide (a), in the presence of 0.15 μ M ethidium bromide (b) or in the presence of 0.7 μ M ethidium bromide (c). For lanes 1–3, both RecA protein and the first incubation were omitted; for lanes 5–7, the first incubation in complete reaction mixture was carried out for 50 min at 37°C. The period of the second incubation with topoisomerase was 20 s (lanes 1 and 5), 5 min (lanes 2 and 6) or 15 min (lanes 3 and 7). Lane 4, untreated form I DNA.

fragments and its formation in the absence of homologous fragments was even greater, the former being 30-fold larger (M.I. and T.S., unpublished observation). However, the formation of form X DNA does occur at a very low rate in the absence of single-stranded DNA and is slightly stimulated by the addition of heterologous single-stranded fragments, but only if double-stranded DNA substrate is form I DNA (Fig. 2b and Fig. 3, lanes 15, 16). When double-stranded DNA substrate is relaxed DNA (form IV DNA), the formation of form X DNA seems to require homologous single-stranded fragments (T.S. M.I. and T.O., unpublished observation, and A. M. Wu, and C. M. Radding, personal communication). These results suggest that the unwinding of the double helix by RecA protein might be initiated at all D-loop sites and also initiated at a very low rate at the transient denatured sites in superhelical DNA³¹⁻³³. The initiation at the latter sites is stimulated by any single-stranded DNA (data not shown) as the unwinding in the presence of ATP γ S (ref. 23).

The enzymes which catalyse unwinding of the double helix in the presence of a high-energy cofactor such as ATP are called DNA helicases, and include DNA helicase I, II (refs 34-36) and III (refs 37, 38) from *E. coli*, *E. coli* Rep protein³⁹⁻⁴² and ATP-dependent DNases from *E. coli*⁴³⁻⁴⁵ and *Haemophilus influenzae*⁴⁶. As a DNA helicase, RecA protein is unique; it unwinds closed-circular DNA without strand termini, whereas all other DNA helicases require a single-stranded tail, gap or free end in the DNA to initiate the unwinding of the double helix. Moreover, RecA protein has not been found to initiate unwinding from a single-stranded tail or gap (ref. 47 and R. P. Cunningham, unpublished observation). DNA helicase activity of RecA protein seems to have a role in the elongation of heteroduplex joints by RecA protein *in vitro*¹⁰⁻¹² and in branch migration during recombination *in vivo*¹⁵.

The present study also indicates that closed-circular double-stranded DNA with an extraordinarily large number of negative-superhelical turns can be formed in physiological conditions by the two proteins, RecA protein and topoisomerase I. In eukaryotes in which gyrase activity has not been found, RecA-like protein⁴⁸ and topoisomerase I might promote a high degree of supercoiling.

We thank Dr Jean M. Michalec for reading the manuscript, Drs C. M. Radding and W. K. Holloman for communicating their results before publication and Dr C. M. Radding for stimulating discussions. This study was supported in part by a grant from the Science and Technology Agency, Japan, and by a grant from the Ministry of Education, Science and Culture, Japan.

Errata

In the letter 'Curare can open and block ionic channels associated with cholinergic receptors' by A. Trautmann *Nature* **298**, 272-275 (1982), the symbols in Table 1 representing the different types of transitions observed should be rotated through 180°.

In the letter 'Electrical stimulation of hindlimb increases neuronal cell death in chick embryo' by R. W. Oppenheim & R. Nunez *Nature* **295**, 57-59 (1982), in Fig. 2 the bars representing pooled data should be labelled CE & SE (left-hand bar) and CU & SU (right).

Corrigenda

In the letter 'Differences in the kinetics of rod and cone synaptic transmission' by J. L. Schnapf & D. R. Copenhagen, *Nature* **296**, 862-864 (1982), the plots of the equation shown in Fig. 1 legend (that is, in Figs 1c, 2c and 3) do not have large enough undershoots. This in turn leads to an overestimate of the decay time of the impulse response. The impulse response actually falls to 1/e its peak value in 80 ms for the rod synapse and 10 ms for the cone synapse (not 131 ms and 16 ms as stated in the second-to-last paragraph). The major conclusions of the paper remain unchanged: the synapses display high and low pass filter characteristics and the rod synapse is approximately 10 times slower than the cone synapse.

In the letter 'Directed effector cells selectively lyse human tumour cells' by C. B. Simone, *Nature* **297**, 234-236 (1982), line 16 on page 236 states that "direct effector cells... cause no adverse reactions *in vivo* (mice and one human)." Instead of "no adverse reactions", the author should have stated that the patient did have two fevers during the five day treatment which responded to acetoaminophen. However, no other toxicities were noted. Obviously, a full trial needs to be done to explore the efficacy of directed effector cell treatment.

BOOK REVIEWS

World on a ledger

Timothy O'Riordan

It is worth casting one's mind back ten years. Oil prices were about \$2 a barrel; OPEC was in existence but seemingly compliant to Western interests. There had been a number of years of unprecedented economic prosperity in most Western and some Third World countries, though the Soviet bloc was experiencing its perennial economic tribulations. Prospects of widespread affluence and material comfort appeared almost a reality.

The only flies in the ointment, it seemed, were that environmental quality (however defined) was palpably worsening and fears of resource scarcity were rife: yet economists continued to tell their political masters that there need be no resource-scarcity limits to growth. This left the "environmental problem" and that was to be tackled at the United Nations Conference on the Human Environment held in Stockholm in June 1972. This conference was full of fanfare and noble rhetoric. If it did nothing else it showed that environmental protection was as much a political issue as a scientific one, and that poverty and environmental destruction were as much interlinked as affluence and environmental mismanagement.

The Stockholm Conference spawned the UN Environment Programme, a rather sickly fledgling which had to find a niche in "far off" Kenya, and a purpose. Over the past ten years UNEP has suffered setbacks as well as experienced some achievements, but in general its main problem is to convert an unwieldy bureaucracy into really meaningful action. Where it has proved its worth, however, is in the monitoring of global environmental problems and processes (notably with respect to chemical cycles and chemical transfers within these cycles) and in its encouragement of international scientific collaboration over matters of global and regional environmental concern.

This book is a fine testament to those important achievements. Its aim is to produce a scientific audit of how the global environment has altered over the ten years since the Stockholm Conference. To this end UNEP devoted considerable effort to commission reports from a large number of scientists, official and non-governmental bodies, established a Senior Scientific Advisory Board to manage the operation and asked three distinguished scholars to edit this awesome mountain of material into a comprehensive and comprehensible synthesis. A particular feature of this book

The World Environment 1972-1982: A Report by The United Nations Environment Programme. Edited by Martin W. Holdgate, Mohammed Kassas and Gilbert F. White. Pp.637. Hbk ISBN 0-907567-13-4; pbk ISBN 0-907567-14-2. (Tycooly International, Dublin: 1982.) Hbk £50, pbk £25.

lies in its almost encyclopaedic factual approach: graphs, tables and statistics abound. It also concentrates on a backward look. This is not one of the ever more prevalent "think tank scenario productions" with myriads of graphs looking like the coloured tails of an aerobatic team. Insofar as it is possible to maintain scientific objectivity, the editors have been successful, and they frequently point out when data are unavailable, difficult to interpret or based on poor experimental evidence.

The book itself is in three parts: the first is concerned with sectors of the physical environment — the atmosphere, marine water, inland water, the lithosphere and its mineral resources, the biosphere and its resources of food, fibre, timber and fuel. Trends in pollution, productivity, human use and other major features are noted, the capacity of the various environmental systems to cope with present demands upon them are also analysed, and both national and international efforts to safeguard these environmental systems are described in some detail. The second part concentrates on human use patterns — on population distribution and growth, on changing patterns of health and disease, and on the conditions of major settlements. The third section covers major human activities affecting environmental systems — industrial developments, the generation and transmission of energy, transportation and tourism.

Collectively the authors are convinced that lack of understanding rather than lack of skills is the one main reason why environmentally sustainable development cannot proceed, and devote an important chapter to recent efforts to upgrade environmental education. They are equally convinced that global survival cannot be guaranteed so long as the present diversion of resources towards military training and increasingly destructive armaments (both conventional and nuclear — though the distinction is now more blurred) continues. So they include a chapter on the ecological and economic consequences of wars

through the 1970s and to the environmental implication of both nuclear and chemical/biological warfare. The authors are not optimistic about the much-longed-for reduction in the arms race with its liberating release of resources and cash for desperately needed environmental improvements. In this chapter, as in the rest, they display an impressive grasp of the key issues and a precise analytical clarity which deserves much praise.

The editors' conclusions are both sobering and hesitant. They confess that, though much has been done over the past ten and more years to improve understanding of the main environmental systems, there are still serious gaps in both scientific understanding and the data base. They note especially the shortage of reliable quantitative information about environmental changes in the developing world. In other respects what data are available can only be described as preliminary (e.g. tropical forest loss and especially the ecological implications of this loss). Similarly detailed estimates of the increase of the desert margins are not yet available, nor are there reliable statistics on the incidence and spread of major diseases. They observe (p.623) that

even an imperfect series of environmental statistics, drawing together what we have (and, through its manifest inadequacies, providing a stimulus to better observation) would be an improvement on the present situation.

A second important conclusion from this study is the essential physical unity of the global ecosystem in terms of biochemical cycles. Each of these interact and hence each is affected by human use and misuse in a most complex manner. But how these interactions work and what will be the consequence if current alterations to these cycles continue simply are not known.

The editors' conclusions are also sobering, because enough is known to cause us all to take the matter very seriously yet the global community of nation states does not appear to want to respond. Ten years after Stockholm the world is in a very different state. Economic recession is almost universal, unemployment is growing almost everywhere and prospects for the citizens of tomorrow, in terms of jobs, wealth and leisure as conventionally defined, look dim indeed. Economic recession has also led to attempts to cut public expenditure. In such an atmosphere international organizations operating

seemingly at the periphery of global economic interests are most vulnerable. Thus UNEP itself is threatened (see *Nature* 3 June pp.348–350). Its budget is declining in real terms and it has failed to co-ordinate the efforts of the various UN agencies, jealous to protect their own sand boxes.

Sadly, this extremely valuable book is symbolic of the failure of UNEP. It is detailed and scientific, steering clear of tackling head on the political necessities for action: it looks backward most of the time but when it peers into the future it only sees uncertainty and ambiguity — two qualities that are readily exploited by politicians living for short term expediency. Finally, the book is an expensive encyclopaedia and as such inaccessible to those lay people who would most want to read it. Those wanting a more accessible document covering much the same material, though in a more political context, should read Erik Eckholm's *Down to Earth* (Pluto Books, 1982). □

Yeast biography

J.M. Mitchison & P.A. Fantes

The Molecular Biology of the Yeast Saccharomyces: Life Cycle and Inheritance. Edited by Jeffrey N. Strathern *et al.* Pp. 751. ISBN 0-87969-139-5. (Cold Spring Harbor Laboratory: 1982.) \$75 (US), \$90 (elsewhere).

FOR at least a century, yeast has been as interesting to the biologist as it has been important to the brewer, the wine maker and the baker. This interest has increased markedly in recent years as it has become clear that yeast can provide a good model for events taking place in other and higher eukaryotic cells. In particular, genetic manipulation has become relatively easy because of the "good" genetics of yeast, the development of hybrid plasmids which will grow both in yeast and *E.coli*, and efficient methods for transformation.

This excellent book is a sign of the times — perhaps only half a sign, since the second, companion volume on metabolism and gene expression is not due until the autumn. The two books will not provide a comprehensive survey of the biology of yeast since they omit a number of topics, including the applied aspects; but they do cover many of the exciting areas of modern yeast research and there is no question of the value of this first volume. The articles are written by experts and will remain definitive statements for at least

several years, even in fast moving fields. They are a good deal more than references hung on a thin thread of text, and many of them include "overviews" which will be especially valuable to the non-specialist.

The longest article is a comprehensive account by Dujon of the dense and complex field of mitochondrial genetics. The shortest is by Roman who gives a succinct historical review of yeast genetics pointing out that it precedes the genetics of *E. coli* by more than ten years. Mortimer and Schild describe the methods of genetic mapping and provide a valuable and up-to-date map of 312 genes on the 17 chromosomes (and fragments) of *S. cerevisiae*. Fogel, Mortimer and Lusnak review the problem of meiotic gene conversion with the delightful sub-title of "Wanderings on a Foreign Stand". Their contribution is for the experts but includes a nice section on the possibility of using chromosomes modified by recombinant DNA techniques to ask direct questions about polarity and conversion. Herskowitz and Oshima give a clear and concise account of the mating type system; this is an outstanding review of the genetics and molecular biology of a fascinating aspect of yeast biology. Esposito and Klapholz deal with meiosis and ascospore development in a good article which includes a number of peripheral topics. Haynes and Kunz review the question of DNA repair and mutagenesis — a complex area which will become increasingly important in the future.

At the slightly higher level of cell physiology and cytology, Byers gives an authoritative account of the ultrastructure of the yeast life cycle where there is a real mystery in the existence of a mitotic spindle without condensed chromosomes. Perhaps this is because of the absence of H1 histone, as Fangman and Zakian suggest in their interesting review of genome structure and replication. Thorner describes the intriguing pheromones of budding yeast; these regulatory proteins "phase" cells of the opposite mating type. There is an article of high quality on the cell cycle by Pringle and Hartwell, who analyse the results from *cdc* mutants and come to a conclusion about cell cycle controls which is more complex than earlier ones. The "circuitry" of the cell cycle has proliferated into a series of parallel pathways and some of the elegant simplicity of the earlier models has been lost — but this is a criticism of life rather than of the authors.

Although the title firmly restricts the book to *Saccharomyces*, it is a little sad that there are not more comparisons both with other yeasts and with other eukaryotic cells. This, however, is a minor point. The major one is that this important book should be available to all who work with yeast and related cells. □

J.M. Mitchison is Professor and P.A. Fantes a Lecturer in the Department of Zoology, University of Edinburgh.

Monocot characters

Peter D. Moore

The Monocotyledons: A Comparative Study. By Rolf M.T. Dahlgren and H. Trevor Clifford. Pp.378. ISBN 0-12-200680-1. (Academic: 1982.) £48, \$98.50.

A COMPREHENSIVE survey of the taxonomic and phylogenetic classification of the Monocotyledones has long been needed. Perhaps it is the sheer size of the task which has deterred prospective authors, together with the wide range of techniques and evidence which is now available to those who wish to investigate evolutionary relationships.

Happily, this task has now been undertaken and it has been tackled in an ambitious and refreshingly novel manner. The bulk of this well-illustrated book is taken up with a "survey of the distribution of selected characters and their states" within the monocotyledons. Here the authors begin with vegetative morphological characters (such as bulbs, petioles, leaf-venation), progress through reproductive features (floral structures, pollen morphology, fruit types) and then consider biogeographical and physiological characteristics (salt tolerance, cyanogenesis, secondary compounds and so on). Within each of these sections the occurrence and variation of that feature within the monocots is considered and often its distribution in the group is illustrated using ordination-type diagrams of floral orders.

Finally, the classification of the monocots is considered in the light of these character analyses. The proposal of the authors is that 26 orders should be recognized, of which 11 contain just one family and a further 7 two or three families only. This may be regarded as the outcome of undue splitting, but three alternative systems are presented which permit higher levels of fusions, at the extreme recognizing only 16 orders. Also, relationships with allied dicot groups are kept firmly in mind.

This is a novel work which has broken with traditional taxonomic treatments by approaching the study of the monocots via characters rather than by dealing with proposed orders in a systematic fashion. This will prove particularly valuable to those who may have interests in specific morphological or physiological traits, from ovule types to saponins, or even in such topics as fungal or insect host-specificity. Not only does this arrangement make it possible to extract information simply and rapidly, but it also provides a rational and objective approach to the final synthesis, giving equal weight, as it does, to all of the varied lines of evidence which are now available to assist in the classification of the monocotyledons. □

Peter D. Moore is Senior Lecturer in the Department of Plant Sciences, King's College, University of London.

Interpreting the rocks of deepest Africa

H.B.S. Cooke

Crustal Evolution of Southern Africa: 3.8 Billion Years of Earth History. By A.J. Tankard *et al.* Pp.524. ISBN 0-387-90608-8/3-540-90608-8. (Springer-Verlag: 1982.) DM118, \$55.

THE systematic geological study of South Africa began before the middle of the nineteenth century and the first map of the Cape Colony by Andrew Geddes Bain appeared in 1852, by which time he had already worked out the essential Phanerozoic stratigraphy. Mineral exploitation subsequently showed the importance of the Precambrian and much attention has been devoted to unravelling the tangled skein of "basement" geology. It is only in the past decade or so that emphasis has shifted from a largely descriptive and stratigraphic attack to more detailed studies concerned with provenance and environmental interpretation. Tankard and his collaborators have produced a volume in keeping with this modern view, one that is radically different from the traditional text on regional geology; their approach is highly interpretative, strongly process-orientated and stresses the dynamic evolution of the crust. The work is dedicated to the great South African geologist and pioneer protagonist of continental drift, Alex L. du Toit, and he would certainly have enjoyed it.

The area covered is essentially the tip of the African continent south of about 16°S, embracing the Republic of South Africa and the adjoining territories of Namibia, Botswana, Lesotho, Swaziland and Zimbabwe. The introductory chapter outlines the basic tectonic framework and delimits the boundaries of major structural "provinces" that underlie the relatively undeformed cover sequences, some of the latter being as old as Late Archean. Each province is a geographical region that shares a number of geological parameters — notably the predominant radiometric age and metamorphic style — the sum of which differentiate the region from the adjoining ones. Thus the provinces are not "cratons" separated by "mobile belts", for the mobile belts of one age commonly become the cratons of a later stage. The Sand River Gneisses in the Limpopo Province south-east of Messina have been dated at 3.8 Ga and are some of the oldest rocks known on Earth; hence the subtitle of the volume. Thus the chronology of the region is a particularly long one.

For the subdivision of the Precambrian, the authors have chosen to use the standard international divisions, Archean and Proterozoic (with Early, Middle and Late subdivisions) rather than employ the regional units adopted by the South African Committee for Stratigraphy (SACS — see Handbook 8 of the Geological Survey of South Africa, 1980).

Although this may be palatable to the international readership, it is a little unfortunate as the SACS units were selected because they are "natural" local divisions and, in point of fact, correspond well with the stages into which the authors divide the evolutionary history of the South African crust. Thus their Stage 1, "Archean Crustal Evolution", does not cover the Late Archean but does correspond to the Swazian, while Stage 2 is labelled "Early Proterozoic Crustal Development" but includes the Late Archean; it corresponds to Randian plus Vaalian. In some other respects, however, the authors use of supergroup where the SACS scheme employs "sequence" (e.g. for the Karoo) is decidedly an improvement.

The text is divided into sections, each of which is devoted to one of the five major stages. Within each section the treatment is generally similar with chapters that deal primarily with a characteristic terrain and a particular province. For example, Chapter 2 is entitled "Granite-Greenstone Terrane: Kaapvaal Province" and incorporates discussion of the now classic Swaziland supergroup, although it does also include some consideration of the Zimbabwe province.

Throughout the volume there is a tendency to provide more petrologic and geochemical data for igneous and metamorphic suites than there is descriptive material for sedimentary sequences, for which only a minimum of stratigraphic or lithostratigraphic data are provided and emphasis is strongly on depositional environments and basinal analysis. The text is thus unusual in its stress on processes and causes, employing the interrelationships between observed structures to unravel the succession of events responsible for the state of the rocks that we now see. On the whole a good balance has been maintained, although the Phanerozoic may be under-played, in marked contrast to the more conventional over-emphasis on this span of geological time.

The illustrations are clear and helpful, although the quality of photographic reproduction leaves something to be desired. Literature coverage is extensive and the authors are to be congratulated on the high quality and up-to-date nature of the synthesis. Not everyone will agree with all of the conclusions and alternative interpretations are not always considered, but this is inevitable with a work of this scope and one must admire the coherence of the whole presentation. It is not easy reading and it is inevitable that many stratigraphic units are mentioned without an accompanying description, so a companion stratigraphic text (such as the recent SACS volume) would be useful for reference.

The book was written, as the preface states, "for advanced undergraduates, graduate students, and professional geologists worldwide". For all of them it should provide a new perspective and an essential tool. □

H.B.S. Cooke was until recently Carnegie Professor of Geology at Dalhousie University, and is now a geological consultant in British Columbia. He was for many years on the staff of the University of Witwatersrand, Johannesburg.

The little bang

R.G. Evans

Inertial Confinement Fusion. By James J. Duderstadt and Gregory A. Moses. Pp.347. ISBN 0-471-09050-6. (Wiley: 1982.) £36, \$64.50.

ALTHOUGH the intensive research effort now being devoted to controlled thermonuclear fusion may appear to be a consequence of the current emphasis on energy projects, the basic ideas date back to the early 1950s. The main approach to the problem of heating and confining a plasma at a temperature of one hundred million degrees has been to use a large and suitably shaped magnetic field. These magnetic confinement machines, for example the JET machine now being built at Culham, are relatively close to the conditions needed for net energy production. But there are still problems with the toroidal geometry for a reactor system, particularly regarding maintenance, and the breeding of tritium to replace that used up in the thermonuclear reactions.

An alternative approach to fusion is not to confine the plasma at all but to utilize the reactions that occur before the plasma pressure overcomes its inertia and it blows apart, hence the slight misnomer of inertial confinement fusion (ICF). At one extreme this technique has been proven with devastating efficiency in the thermonuclear or hydrogen bomb. To reduce the explosive yield of a hydrogen bomb to manageable proportions requires the rapid compression of a small pellet of deuterium/tritium fuel to densities of a few hundred grams per cubic centimetre. The technical means to do this were not available until the advent of high-power lasers in the late 1960s and the major declassification of inertial confinement fusion occurred in 1972. There was early optimism for "break even" experiments with fairly modest lasers and this spurred on laser development programmes in the United States, the Soviet Union and to a lesser extent Japan and Europe. The promise of the early theoretical predictions has been somewhat tempered in the light of experimental testing, however; the current

laser fusion projects are as expensive as the large magnetic machines.

Despite much activity in this field, it has taken ten years for the first book to appear dealing with the whole range of physics involved. *Inertial Confinement Fusion* gives a commendably comprehensive coverage of the subject dealing for instance with the thermonuclear reactions themselves, plasma physics, hydrodynamics, lasers, particle beams and reactor problems. The book is very thorough on the different driver systems and describes high power lasers, relativistic electron beams, and both light and heavy ion drivers. In dealing with such diverse topics the book will inevitably leave many readers dissatisfied with particular details. For instance the section on laser plasma interaction fails to deal adequately with the important areas of stimulated Raman and Brillouin scattering, and the problem of symmetry of compression is barely touched upon. It would also have been invaluable to have examined the reasons for the failure of laser fusion to fulfil its early promise.

Several factual errors have crept in through an apparent zeal for making the information as up to date as possible; some ICF facilities are declared to be in existence when they have yet to obtain full financial approval. The book is generally very readable, however, and has its lighter moments — for instance the definition of “anomalous” as meaning inadequately understood, and the reference to “the thrilling days of yesteryear” in relation to heavy ion fusion where the high cost of experimental hardware has so far shielded the theory and computational predictions from the rigours of reality.

Aside from these criticisms the book fills a large gap in providing graduate research workers with an up-to-date description of a wide ranging field. There is a large number of references, although these are mostly to work in laboratories in the United States, and perhaps too large a fraction are to internal laboratory reports which might not be widely available.

“The power of the stars” may not yet be with us, but at least Duderstadt and Moses have confronted us with most (though not all) of the problems of the inertial confinement approach to fusion. □

R.G. Evans is at the SERC Central Laser Facility, Rutherford Appleton Laboratory, Chilton, Oxfordshire.

Archaeoastronomy

Papers presented at the archaeoastronomy symposium held in September last year at Queen's College, Oxford (reported by Aubrey Burl in *Nature* 293, 335; 1981) have been published in book form by Cambridge University Press. The proceedings have been divided between two companion volumes, *Archaeoastronomy in the New World* (edited by A.F. Aveni) and *Archaeoastronomy in the Old World* (edited by D.C. Heggie). Prices are £16, \$29.95 and £20, \$37.50 respectively.

Gell and Coombs for the nineteen eighties

Fred S. Rosen

Clinical Aspects of Immunology, 4th Edn. Two volumes, pp.1,751. Edited by P.J. Lachmann and D.K. Peters. ISBN 0-632-00702-8. (Blackwell Scientific: 1982.) £90, \$195.

IMMUNOLOGY started as a clinical science two centuries ago in rural Gloucestershire. A hundred years later Pasteur gave the subject renewed impetus by his studies in chickens. In recent decades the greatest progress in illuminating the arcana of the immune response has come from the study of inbred strains of mice, and the clinical aspect of immunology has almost become a quiet backwater of the subject. So this revised and expanded edition of “Gell and Coombs” classic work is welcome addition to the slim space on library shelves devoted to the clinical aspects of immunology.

The first volume consists of 744 pages of basic immunology and the second of 1,006 pages of the clinically relevant applications of immunology to disease entities. Because of the nature of the subject matter the first volume is the more cohesive and satisfying of the two. It starts with six succinct chapters on the relevant globulins and cells of the immune response. The illustrations and diagrams are copious and germane to the text and each chapter ends with a useful list of references, features which remain consistently good throughout the work.

The second section in Vol. 1 is devoted to a discussion of cellular interactions and contains a unique contribution from J. H. Humphrey on the fate of antigens. Two further sections are concerned with technology that is clinically relevant, such as radioimmunoassays, rosette-forming

reactions, detection of immune complexes, tissue typing and monoclonal antibodies, and with the limited approaches to suppressing or stimulating the immune response. The final section of the first volume ends with a presentation of the pathophysiology of allergy and immune injury. Special praise is due T.A.E. Platt-Mills for his comprehensive, if not exhaustive, presentation of immediate hypersensitivity. This contribution is a mini-textbook on its own and the best current presentation of the subject matter that I know of.

The first volume is a hard act to follow, but although Vol. 2 is more uneven it in the main sustains the high quality of its companion. It deals with organ-specific immunologically-mediated disease, rheumatology, transplantation and infection. Although the text is purported to be written in English, jargon such as “... patients with NPC have high titres of anti-D, and certain patients with BL have high levels of anti-R” leave the reader groping to decipher the meaning.

This text, like all scientific and medical works these days, is expensive but it is well worth the cost to all those who practise clinical immunology. It is more current and broader in its coverage than the two other multi-volume competitors in the field. In an arena of rapidly expanding information, Lachmann and Peters have done a superb job of comprehensively assembling the diverse subject matter that constitutes the clinical aspects of immunology. □

Fred S. Rosen is the James L. Gamble Professor of Pediatrics at Harvard Medical School.

Harrison Schmitt in the valley of Taurus-Littrow during the Apollo 17 mission to the Moon. During their 22 hours of exploration Schmitt and Eugene A. Cernan investigated the major geological formations in the valley and collected 110 kg of rock and soil samples, including a 3m core — material which among other things provided new data on the early crustal history of the Moon. The picture is taken from *The Solar System and Its Strange Objects*, edited by Brian J. Skinner, a new addition to the series *Earth and Its Inhabitants: Readings from American Scientist*. What kind of crisis for capitalism?

This week's meeting of the International Monetary Fund at Toronto will avoid an immediate crisis. But more international credit will not allow rich and poor to behave as if they live on different planets.

A few weeks ago, the International Monetary Fund put out a document that argued persuasively that inflation is an evil that the international community must somehow conspire to destroy. This week, in Toronto, the members of the fund will have arranged to do the opposite. Whether they agree that the amount of credit available internationally through the fund should be doubled (as the developing countries would prefer), increased by only a fifth (as the United States has been insisting) or will compromise somewhere in between is in a sense immaterial. What matters is that any increase in the money available to the fund will be potentially inflationary. Indeed, in present circumstances, any increase of the fund's ability to lend money will probably encourage inflation. So why have the members of the fund so quickly rejected the advice their organization was putting out in August? Because they have no choice.

The International Monetary Fund, one of the last creations of John Maynard Keynes, is not a bank in the strict sense but only a kind of bank. Its objectives were originally to deal with the problems that must arise from time to time in a world in which trade is free and when governments find themselves in financial difficulties. As with any other bank, the fund will then step in with a helpful loan, usually with strings attached (devaluation, fiscal probity and so on). The fund is not however a bank in the strict sense, because people (or governments) are not forever asking it to look after their money. Instead there is an arrangement under which the fund can call on its members to stump up a contribution if it thinks the time has come to lend. For the past quarter of a century, the system has worked well, justifying Keynes's advocacy of its necessity.

This week's decision in Toronto will break new ground in the history of the fund, and may even spell its end. A little recent history is relevant. When the price of oil was first drastically increased in the second half of 1973, the world's financial community seized on two immediate problems — the huge size of the financial surpluses that would accrue to the oil exporters and the plight of those developing countries that had neither oil nor the export capacity with which to buy it. In the event, the problems cancelled each other out: the oil-exporting countries lent their surplus funds to the commercial banks in the industrialized countries which then proceeded to lend on those funds to the countries that could not afford to buy oil, or the products that oil would make. Until a few months ago, this *ad hoc* system appeared to be working well. What has gone wrong is the discovery that many Western commercial banks have lent so much money to so many shaky creditors that some of them are in danger of going bust. The reasons why the members of the International Monetary Fund will have agreed this week on some increase of its lending capacity are simply that they cannot let their own commercial banks collapse under the weight of unpaid foreign debts. The snag, of course, is that neither the fund nor its member governments will be better able to control what happens now than the commercial banks have been.

The explanation is that the debtor countries have not been living as if to qualify for a loan from the International Monetary Fund. Rather, they have been borrowing from those commercial banks gullible enough to lend to them in the hope that they might avoid trouble for another few years — latterly, months or weeks. Yet every commercial branch manager knows that it is imprudent

to lend money to help a customer pay the rent, but that helping the customer, by capital investment, so as to be better able to do so is expedient and also socially beneficial. The International Monetary Fund is no longer in a position to require such a discipline from its creditors. First, its leverage as a quasi-bank has shrunk — in twenty years, its capacity to lend has shrunk by more than a third in relation to the monetary reserves of member states. Second, habituated as they are to living beyond their means the clients of the fund are neither willing nor able to cut back.

That is why this week's decision in Toronto cannot but be inflationary. Some clients of the fund will borrow money within the next eighteen months, will use it conveniently to repay their debts to the international commercial banks, but will not be able to promise that they will also promptly put their affairs in order. Who would reasonably ask of Mexico (see page 99) that it should deal quickly with these issues when its newly elected government cannot constitutionally take office until 1 December? And what is to happen to Argentina, unable to make a deal of any kind because the British Government has not been given proof that the Falkland Islands war is over? And then, worse still, what is to happen to those countries that have been buying oil for the past decade, but which have been unable to persuade banks of any kind of their credit-worthiness? Self-deprivation has allowed them to survive so far, but only passably. How far can self-deprivation be expected to go?

The Toronto meeting of the International Monetary Fund has frequently been described as a crisis of capitalism. It is nothing of the kind. Rather, it is the opposite — the occasion of the rediscovery of what nineteenth-century economists had to say about people's (or countries') interdependence. Chase Manhattan, or some other commercial bank, might be able to make Mexico (or some other country) bankrupt, but would then have to go to the wall itself. Middling governments such as those of Britain and West Germany may embark on policies intended to cure inflation domestically but then find themselves having to fuel it because they cannot stomach the consequences. Mitterrand's France may even have to acknowledge that its alliance of socialism and the printing-press cannot endure. And Reagan's United States may have to acknowledge that a \$100,000 million deficit is a recipe for beggaring its neighbours. So what the world needs is not a substitute for capitalism but some way of melding fiscal probity with an acknowledgement that neither the poor nor the rich can these days go it alone. Keynes, where are you now?

Paying for nuclear plants

Should US utility customers pay now or later for new nuclear plants? The utilities wrongly say now.

The substantial crop of nuclear power plants due to come into service in the United States in the next few years will have an unprecedented effect on the price paid by customers for electricity. Many customers are facing rate increases of 30 per cent, customers of one utility, Kansas Gas & Electric, will be charged 60 per cent more when the Wolfe Creek reactor comes into service in 1984. The utilities are seizing on these proposed rises as an opportunity to seek a major change in the way plant construction is financed. But the change they propose — charging

consumers for construction costs as they accrue, before the plant is in operation — is short-sighted and will benefit nobody

Commercial utilities in the United States are subject to strict state regulation, in most states the time-honoured principle of charging customers only for plant equipment that is "used and useful" is the rule. The utilities argue that the rule is outmoded. When nuclear plants used to cost a few hundred dollars per kilowatt and when interest rates were a few per cent a year, the addition of a new plant barely caused a ripple. Indeed, the savings in fuel costs would often outweigh the capital costs of a new nuclear plant, resulting in a decline in the price to customers. But costs have now reached staggering heights. A new nuclear plant, with a typical capacity of 1,000 megawatts, costs more than \$2,000 million, ten times as much as in the 1960s. High interest rates and construction delays add to the cost eventually charged to the consumer — whence the 30 per cent increases. The utilities want the right to charge consumers as they go. This "Construction Work in Progress" charge (CWIP) would be used to pay the dividends due to bond and stockholders during the period of construction. It would also result in a gradual phase-in of the price increase. Without CWIP, the utilities say, they have to borrow money to pay the bonds that become due during construction, and the extra cost of borrowing is ultimately passed on to the consumer once operation begins.

The utilities seem to have overlooked the principle on which the regulation of their charges is based — that present consumers should pay only for the services available to them now and not for services that will be available only to future cohorts of consumers. That principle, which underlies the regulation of all rates charged by public services in the United States, could not be overturned just like that to suit the present convenience of the electricity utilities. Moreover, to change the rules arbitrarily would be inequitable in quite tangible ways. For while it is true that by "paying now", a consumer would avoid having to pay for the interest charges accumulating during a construction project, he would then be denied the opportunity of investing the extra payments on his own account. "Pay now" costs at least as much as "pay later".

Although "pay now" seems to solve the utilities' immediate problems (not the least of which is the public relations problem of asking for 60 per cent increases), it glosses over a more fundamental difficulty. According to Professor Michael J. Driscoll of Massachusetts Institute of Technology, "the real solution is not to play around with CWIP, it's to get back to a reasonable construction schedule". Building nuclear plants used to take six years from start to finish, in France, they still do. But in the United States they now take 10 to 12 years. And the utilities' scapegoat — government delays in issuing licences — is only partly to blame. Driscoll points to inefficient management and the practice of custom-building each new reactor. France has seen the wisdom of that American innovation, mass production. But every delay increases the interest costs accumulated during construction, and the utilities would gain more by solving this underlying problem than by covering it up with CWIP charges.

Bluntly the burden of paying a 30 per cent or 60 per cent increase in prices is less for society as a whole than paying ahead of time for a nuclear plant that is not needed. The present system has the virtue of forcing the utilities to persuade bankers and investors that future demands will justify the next 1,000 megawatt power plant. The "pay now" policy, on the other hand, allows the utility to pass off some of the risk of its venture onto its consumers. And the track record of the industry in predicting future demand suggests that the consumers would be forced to make some bad investments. The industry has been notoriously optimistic — in 1974, the Edison Electric Institute (the commercial utilities' trade group) predicted a total US energy demand of 160 quads by the year 2000. By 1976, it was 140. In 1980, Exxon Corporation was saying 105. With the demand for electricity at a near standstill (rising only 0.3 per cent in 1981, in contrast with 7 per cent per year throughout the 1960s and early 1970s), the need for cautious planning is obvious. The marketplace should be allowed to continue to exercise a check on new power plant construction.

Press's forgotten recipe

Does the US scientific community consider Dr Frank Press's cure unpalatable?

Strange as it may seem, people have been ignoring Dr Frank Press, president of the US National Academy of Sciences. Press has had the temerity in the past six months to propose a long-term cure for the ills of US science. He has been observing that in these unprecedented times, federal funding on science has become part of the vulnerable discretionary federal budget and thus vicariously liable to cuts. What has happened this year, with the executive branch and Congress still haggling over money for the year that begins on 1 October, may be symptomatic of what is to come. So, Press says, the science community should negotiate a pact with government and industry to insulate science, to stabilize funding and to ensure that talented young scientists have opportunities.

In Press's five-point plan, government would agree to assured increases each year in the budget for basic research at a rate that would cover inflation and allow an extra 2 per cent of real growth. This "base programme" would be government policy. It would not rule out larger increases, but would ensure that overall funds did not fall below this level. Government should commit a further 1 per cent each year to "targets of opportunity", for research related to national needs or for new facilities. At the same time, industry would agree to double its present total contribution of \$50 million and would also start, with the government, a new fellowship programme. A central agency, perhaps the National Academy of Sciences, might serve as a collection and distribution agent, although the funds would be spent in fields where shortages are likely and selection could rest with individual agencies. A comparatively small amount of money, say \$10 million, would buy a thousand fellowships.

The nub is in the last of Press's five points. Scientists themselves, he says, should be able to find another 2 per cent by setting priorities within their own fields and by cutting out unproductive work. Then, the argument goes, universities could persuade government to ease regulations, such as the notorious Office of Management and Budget regulation on accountability, and let them keep the savings. Based on the estimated \$7,000 million the government spends on basic science and engineering, Press's potential cure could provide an extra \$694 million, an increase of almost 10 per cent, plus the use of up to \$114 million in funds that have been reprogrammed. But where should the extra money come from? Press suggests that the government should raid the development budget where, he believes, there is a lot of waste. (The Clinch River breeder reactor programme consumes about \$600 million each year, development of the B-1 bomber about \$700 million a year.)

The weakness of the plan is Press's assumption that scientists will centralize their lobbying efforts in Washington upon the single cause of a guaranteed overall increase. (Another is that Congress is all too familiar with special groups seeking to convert appropriations into entitlements.) Success for the plan would, however, bring predictability to the support of basic research and put scientists to work setting their own priorities, not leaving that to officials in Washington. And, of course, nothing in what Press has been saying suggests that the government has at this stage agreed that the scientific community could keep whatever savings would accrue from a more rational pattern of expenditure.

So why has the scientific community neglected the challenge? In the peer-ridden US system, changing tack in any direction is difficult. Arrogant specialization does not help. But Press's message is that if the research community cannot decide priorities for itself, the accountants and the lawyers will. Press seems to be echoing what Dr George Keyworth has been saying from the Old Executive Office Building next to the White House, but he has stronger credentials for being taken seriously. Indeed, with his experience of an earlier White House, Press is uniquely well placed to make what he has been saying tell. Why does nobody respond or even listen?

Norway's Arctic diplomatic fix

Poles' defection in Spitsbergen casts shadow

The two Polish scientists who defected last month from the Polish geophysical station at Hornsund (Spitsbergen) have created a delicate diplomatic problem for their Norwegian hosts and something of a crisis for Norwegian Arctic research.

Although sovereignty over Svalbard (the island group of which Spitsbergen forms part) was granted to Norway by international treaty in 1920, by the same treaty Norway undertook that the nationals of the signatory countries (of whom, with later accessions, there are now 41) should be treated on an equal footing with regard to economic activities.

The Soviet Union thus has two coal-mining bases, one near Barentsburg and another at Pyramiden. Similarly, under a memorandum from the Norwegian government to the other signatory states, foreign expeditions have free access to carry out scientific research in Svalbard as well as free access to the information on the islands held by the Norwegian Polar Research Institute.

The Polish research base at Hornsund is staffed by a team of 10 scientists from the Institute of Geophysics of the Polish Academy of Sciences. The research programme includes geological, geophysical, glaciological and meteorological work. A relief expedition, consisting of the 1982-83 scientific team plus a group of technicians to carry out routine maintenance work at the station sailed from Gdynia in July.

On 10 August, two of the scientists (it is not clear whether from the incoming or outgoing teams) decided to ask for political asylum, and radioed the Norwegian *Sysselman* (governor), announcing their intention to report in person to file their applications at the administrative base at Longyearbyen.

This transmission was, however, picked up by the Soviet Union's mining post at Barentsburg, which sent a helicopter to intercept the two Poles who were repeatedly "buzzed". One was driven back to base while the other fled into the hills and returned to Hornsund next day.

When the *Sysselman* heard what had happened, he sent out in his own helicopter to pick up the two would-be refugees, the Soviets, however, realized what was happening and sent their own helicopter to try and reach them first. In the words of one Norwegian official, *Sysselman* won the race, confirmed that the two men still wanted political asylum and took them back with him for questioning to Long-

yearbyen, whence they were dispatched to Oslo for "safe keeping". Their requests for asylum are now being processed, their identities are for the moment being kept confidential.

A number of diplomatic questions remain to be clarified. Military activity on the islands is strictly forbidden under the Svalbard Treaty of 1920, and it could be argued that the Soviet use of their helicopter in what can only be called a third-party police action could be construed as a breach of this agreement.

Furthermore, the Soviet helicopters are supposed to ply only between Barentsburg, Pyramiden and Longyearbyen, while some 44 per cent of Svalbard (including South Spitsbergen, where Hornsund is situated) comes under nature protection orders, where any technological encroachments, including motorized vehicles, are forbidden. Noise harassment of geese and other aquatic birds during the moulting season is particularly hazardous since it can scatter flocks and separate the young prematurely from their parents.

So far, the Norwegian Foreign Office seems concerned to keep the whole incident low-key. For their part, the Soviets can have little wish to fall foul of the Norwegian environmentalists. The Soviet Union extracts some 400,000 tonnes of coal

from Svalbard each year.

At Barentsburg, however, the reserves covered by the Soviet claims patent are almost exhausted, and output is now maintained only on the basis of a leasing agreement with the Norwegian mining company which owns the adjacent areas. A Norwegian Royal Decree of 1971 stipulates that no new mining, oil drilling or other industrial operations can be initiated without a thorough preliminary study of possible environmental consequences.

Vera Rich

Two Soviets banned from Perth

Canberra

The Australian government refused two Soviet scientists visas to attend the 12th International Congress of Biochemistry in Perth on 15-21 August, organized by the Australian Academy of Science under the aegis of the International Union of Biochemistry (IUB). The scientists are Professor Y. A. Ovchinnikov, vice-president of the Soviet Academy of Sciences who was to deliver a plenary lecture, and Professor S. S. Debov, also a member of the academy. Taking umbrage, the other 25 Soviet registrants boycotted the congress. It now appears that the International Council of Scientific Unions (ICSU) may ban Australia as a venue for international conferences at its meeting on 12 September.

The Soviets singled out for exclusion were regarded by the Australian embassy in Moscow as government men rather than scientists. Consequently the banning is consistent with government policy of not allowing high-ranking Soviets into the country. Following the Soviet invasion of Afghanistan in 1979, the government announced a package of sanctions against the Soviet Union, after a cabinet decision in January 1980. These moves included the suspension of a bilateral scientific and technological agreement signed in 1975, and the banning of mutual visits by

ministers and senior officials. A cooperative expedition on a Soviet research ship was called off, Soviet scientists in Mount Stromlo Observatory were sent packing, student scholarships to the Soviet Union were cancelled and visas refused to Soviet agricultural officials. In addition universities were advised to suspend academic exchanges but not multilateral conferences.

After these events, the Australian Academy of Science found itself in the invidious position of having to provide IUB with an assurance that no scientists would be barred. It sought from the government a "form of words" considered to be acceptable to IUB — "bona fide scientists from all countries will be admitted to Australia to attend the conference subject to the normal rules and requirements for visitor entry to Australia in operation at that time." But the then minister for immigration, Mr Ian MacPhee, wrote to the then foreign secretary of the academy, Professor Gordon Ada, in June 1980 — "I should stress that if this form of words is used, it must be understood by the academy that the normal rules in operation at the time of any conference might well exclude a particular scientist, a group of scientists or scientists of a particular nationality. I could not forecast what would be normal in say 12 months or 3 years time."

These reservations were not passed on to IUB. Unfortunately the possibility of Soviet scientists being banned as officials was not considered by the organizers at any time during the interim period. A spokesman from foreign affairs believes the problem could have been overcome by consultations beforehand.

The stage was thus set for the imbroglio at the conference, the first IUB congress in Australia. The Soviet participants waited until the last minute to apply for visas, and just a few days before the conference the ban was announced. Appeals from the president of the Australian academy (Professor Arthur Birch), the premier of Western Australia (Mr O'Connor) and the Swedish Academy were all to no avail. It was too late for the government to back off gracefully.

Reactions at the congress were mixed. Professor Frank Gibson of the Department of Biochemistry, John Curtin School of Medical Research, Australian National University, says "disappointment at not hearing Professor Ovchinnikov's lecture was the main reaction". Lack of travel funds, and the relatively high cost of internal air fares and accommodation limited the number of overseas registrants, particularly from the United States.

The academy now faces the unenviable task of persuading the government to change its policy in the week before the ICSU meeting. Failing this, it will try to delay any precipitate action at the meeting. Nevertheless international censure may be just the prod the government needs to review its policy on sanctions. Significantly, the International Union of Pure and Applied Chemistry succeeded in securing the admission of Israeli scientists into India for a conference on the applications of the Mössbauer effect held in Jaipur last December. **Vimala Sarma**

European space technology

Ariane set to go

The delay to the fifth launch of Ariane, rescheduled from last April to tomorrow, has had its effects on the vehicle's future launch programme. But careful reorganization of the launch schedule up until the end of 1984 seems to have ensured minimal damage to the launcher's commercial prospects.

The five month delay has been caused by problems with Marecs B, one of two satellites that the fifth Ariane will put into geostationary orbit. Marecs B had to be modified after problems with electrostatic charging on Marecs A, the sister satellite launched by the fourth Ariane late last year. The first effect of the delay has been to reduce the number of Ariane launchers this year from four to two. The next launch now scheduled for November will put Exosat, the X-ray observatory built by the European Space Agency, into polar elliptic orbit, more or less on its target date. But the launch of ECS 1, a communications satellite, is being delayed to early next year and Intelsat, the international telecommunications satellite organization, which was to have launched the sixth Intelsat V satellite aboard Ariane in October or December this year, has taken that part of its custom elsewhere.

Intelsat, however, has not reduced its overall commitment to Ariane. The launcher will now put Intelsat V numbers 7, 8 and 9 into orbit next year instead of numbers 6, 7 and 8. Next year's launch programme has been rescheduled to include six launches, the maximum possible with the present launch pad, instead of five originally planned.

Ariane is now fully booked with firm orders until the end of 1984 according to

Arianespace, the company that will take over commercial operation of the launcher some time next year. Just two places remain to be firmly negotiated for 1985 and a number of reservations, for which customers must pay \$100,000, are apparently in hand for future years. But Ariane has now lost some early reservations from customers who have eventually plumped for US facilities and Arianespace acknowledges that the fifth launch of the shuttle in November, which will put a satellite into geostationary transfer orbit, could take the edge off Ariane's seeming attractiveness.

The next few Ariane flights will still be formally in the hands of the European Space Agency. Arianespace will take over operations and start earning revenue from launches from the middle of next year, probably after the tenth flight. The company hopes that by 1985 the capacity of the launch facilities at Kourou in French Guiana will increase from 6 to 12 when the second launch pad, now under construction, comes into operation. Arianespace expects to start showing a modest but respectable profit in 1985. But future prospects will also depend on the success of the space shuttle. The latest estimate is that customers will have little to choose between the two on price. Reliability, service and convenience could be most significant. **Judy Redfearn**

Australian science politics

Labor's policy

Canberra

The Australian Labor Party, more hopeful than ever that it will form the next federal government but less certain now than a few weeks ago that the general election will come soon, formally adopted a new policy on science and technology at its biennial conference here in July. Although the policy is vague enough not to be a constraint on Labor members of parliament, the convention that conference decisions are binding on elected representatives may yet cause trouble.

The new science policy was adopted on the nod on the last day of the conference, when most delegates were packing up to go home. On the face of things, science and technology have only low priority, at least compared with the uranium issue. The conference heard a sustained and embittered debate on the question of whether Australia under Labor would honour existing uranium contracts. That issue remains unresolved, although the conference confirmed the principle that Labor will supply uranium abroad only on tough conditions.

The cornerstone of the Labor Party's policy on science and technology is economic — government spending will bring prosperity and economic growth. Mr William Hayden, the leader of the party, and his colleague with responsibility for

Now even MIT has troubles

Washington

Even well-off US universities are not immune from the financial squeeze affecting US higher education. The Massachusetts Institute of Technology (MIT), which has an operating budget of \$500 million, reports that it had a deficit of \$2 million for the year just ended. Next year's deficit could be \$4 million. Consequently, it has now announced plans to cut costs and, among other things, to lay off 400 employees.

Unlike both the California Institute of Technology and Stanford University, with which MIT is often compared, MIT has a relatively small endowment and thus a harder cushion for hard times. The current deficit is not MIT's first, it had a deficit in the early 1970s, when it lost the extra income and overhead funds that went with the Charles Stark Draper Laboratory, from which it severed its

connections at that time.

According to provost Francis E. Low, approximately two-thirds of MIT's operating budget is composed of funds that come in each year to operate facilities such as the Lincoln Laboratory, with little control or financial benefit to the rest of the institute. To control rising costs, then, the institute must look to the \$120 or \$130 million in general funds that pay for education and its administration. To prevent rising deficits, these activities will have to be reduced. There will be some faculty reduction through normal attrition, causing a loss of approximately 30 positions. Also, 200 other people will be allowed to leave through attrition in the next few years, he says, while an additional 200 will be laid off. Low thinks the institute can afford some belt-tightening. "It [MIT] functions in some respects in a luxurious way." **Deborah Shapley**

science and technology, Mr Barry Jones, have repeatedly said as much.

Perhaps significantly, the present Liberal-Country Party coalition government has responded by increasing support for the Industrial Research and Development Incentives scheme from A\$14 million to A\$50 million. More broadly, the government has taken to justifying a more interventionist approach to Australian industry by references to "market imperfections".

More animal care

Washington

Public pressure for a change in rules governing the care of laboratory animals has prompted the National Institutes of Health (NIH) to tighten up their requirements, whether or not Congress acts on the matter this year.

NIH will require that at least one non-scientist be appointed to each research institution's animal care committee — the groups charged with overseeing the treatment of experimental animals. This echoes one of the requirements in the bill now before Congress. (The bill, renumbered HR 6928, has cleared the House Science and Technology Committee and is now before the health and environment subcommittee of the Energy and Commerce Committee.)

NIH is also planning to mount a series of site visits to check on the extent to which researchers are complying with NIH guidelines. Under current rules, recipients of NIH grants must agree to adhere to the practices outlined in NIH's *Guide for the Care and Use of Laboratory Animals*. Failure to do so can result in loss of NIH funding. A major criticism of the system, however, is that too much reliance is placed on the good-faith assurances of the researchers and too little on inspection.

But NIH is not yet ready to order on its own another change in the proposed legislation: the mandatory accreditation of all research institutions by an independent group such as the American Association for Accreditation of Laboratory Animals Care (AAALAC), which sets standards and conducts routine inspections every three years. According to Dr William Raub, NIH's associate director for extramural research, "We think the concept of accreditation makes a lot of sense. But we're not yet, at least, willing to mandate it until we know more about the costs". Universities have claimed that bringing all NIH-supported institutions up to the AAALAC standards would cost \$500 million. The legislation before Congress would eventually require all institutions to meet the AAALAC standards, but would soften the blow by allowing ten years in which to meet this goal.

Stephen Budiansky

Labor is less inhibited about intervention. The July conference undertook that research and development expenditure should increase from the present 0.9 per cent of gross national product to a level "equivalent to that in other technologically advanced countries". Prudently, Labor did not specify a target figure.

What Labor offers is more pragmatic — a promise of a new division in the Department of Science and Technology to be concerned with industrial research, development and innovation. A Labor government would be a dutiful customer for new Australian products, and would back technical innovations with hard cash. It would also provide venture capital for new kinds of industrial developments, in biotechnology for example.

On issues such as these, the parties differ only moderately. Neither will increase

spending on basic research. The best hope is that Labor would not let research funds be eroded by inflation.

Long-standing disagreements persist, however, about the role of foreign corporations in high-technology industries. Labor would require foreign corporations to carry out some research and development in Australia, but Mr Barrie Jones seems well aware that he must find a form of words not so restrictive that foreign corporations will be driven away.

The new Labor policy also promises innovations to give high relief to Australian science. The conference approved a plan for an "Australia Prize" of A\$100,000 for humanitarian scientific achievement, to be administered by the Australian Academy of Science, and an international conference on Antarctic research to reinforce Australia's claim to the largest slice of the Antarctic.

Mexican science in money trouble

Mexico City

In the face of Mexico's present economic crisis, the country's expensive and ambitious programme for science and technology now faces shocking sudden austerity. "A crisis can be good," says Pablo Rudomín, the distinguished neurophysiologist who is president of the Mexican Academy of Sciences. "It leads you to deep thoughts about where you're going. I think it [the crisis] will give us a sense of community. We'll have to work on priorities, and quality and on preserving what we have."

What has happened is that after a decade when the economy was flooded not just with domestic oil revenues but with loans from foreign banks (chiefly in the United States), Mexico has found that it cannot pay the instalments due on its debts, estimated at \$80,000 million. The payments were rescheduled in August, since when the Mexican banks have been nationalized. All sectors of the economy will have to be cut back, but just how will not be known until the new government of President Miguel de la Madrid Hurtado takes office on 1 December.

"Things will change, but probably for the good," echoes economist Manuel Gollás, who holds a key political post as head of the advisers to the director general of the Consejo Nacional de Ciencia y Tecnología (CONACYT), the Mexican science agency. One irony of the boom, he reflects, is that sometimes "we had more money than we did worthwhile projects".

Supported with government oil revenues and announced with a great fanfare at the beginning of President José López Portillo's 6-year term, Mexico's science and technology programme was designed to strengthen the infrastructure of science and to encourage Mexican self-sufficiency in technical matters. The programme was nothing if not ambitious. Basic research did well, but there were also

special priority programmes in fields such as agriculture and nutrition. The energy programme included work on nuclear and solar energy production. There were schemes for supporting industrial research, and the government had emphasized the importance of training graduate students.

Interviewed in their respective offices in Mexico City, both Rudomín and Gollás acknowledged that the programme had been criticized as being only a shopping list of unrelated projects, reflecting the interests of individuals and government agencies. Indeed, its execution reflected this pattern. CONACYT, which designed

the original programme and serves as the president's science adviser, actually controlled only 11–12 per cent of the total science and technology budget. The government gave the rest directly to universities (the major one being the Universidad Nacional Autónoma de México, whose main campus is in Mexico City). Money for the Instituto Politécnico Nacional, for example, comes from the Ministry of Education. Private industry and foundations play almost no part in sponsoring Mexican science.

More than half of CONACYT's budget for 1981, estimated at 3,899 million pesos, went for scholarships, another 20–30 per cent for administration, public relations, and publications. Grants for basic science directly to investigators in fact accounted

for only 5 per cent of the budget, Rudomín estimates, or 109 million pesos. With other funds, basic research claimed about 20 per cent of the total CONACYT budget.

The science programme built on a major educational effort launched by the government of President Luis Echeverría in 1970 to stress education, including science and mathematics in the Mexican schools (*Nature* 280, p.101; 1979). According to Mexican officials, in 1968–69 Mexico had around 600 PhDs. By 1982, after more than 26,000 scholarships had been awarded, it claims 15,000 technically trained graduates, of which an estimated 6,000 hold a PhD.

Language a barrier

Mexico's ambition of achieving excellence in basic science is complicated by a double-edged language barrier: few scientists in the English-speaking world read Spanish scientific journals, while not many Mexican scientists know English well enough to publish in English-language journals. Even among Latin American countries, Mexico ranks low in the prorated number of its scientific publications in English-language journals, according to one recent survey. Many Mexicans feel it is "traitorous", as one of them put it, to publish in English. The Mexican science agency was sharply criticized when it decided that its fourth publication should be in English. (This is *RD Mexico*, a colour magazine that is suspending publication because of the current crisis.)

Science Citation Index reports that of the 3,068 journals in the index, only 13 are published in Latin America. Of these, 12 are published in Spanish and one is trilingual. Three of the 13 are published in Mexico. Latin America as a whole, therefore, contributes less to the index than does East Germany, which has 40 journals, or Austria, which has 24.

Mexican scientists complain that they are damned either way. If they publish in an English-language journal, their colleagues cannot read it and if they publish in a Spanish journal, their peers abroad will not. Yet English-language journals solve this dilemma for them, they allege, by discriminating against Latin American submissions. One scientist said that he has had an easier time getting his papers accepted by English-language journals when his co-authors have had Anglo-sounding names.

In any event, Mexico has a particular disadvantage on the language question because it did not experience the waves of immigration from European countries (except from Spain) that have admixed the populations of Brazil, Argentina and Chile. Deborah Shapley

One result is that most Mexican scientists are younger than Rudomín, who is in his mid-forties, and his predecessor as president of the Academy, engineer Daniel Reséndiz, who is 42. "Mexican science is not more than 40 years old," says Rudomín. "The first thing we have accomplished is to have trust in ourselves." Rudomín himself returned to work in Mexico after a stint at the Rockefeller University in New York. He has striven, he says, to make other Mexican scientists abroad come home to do good science.

However, the science programme did not succeed in achieving its goal that 1 per cent of the Mexican gross national product (GNP) should be devoted to science and technology. Science and technology have been between 0.38 and 0.47 per cent of the Mexican GNP for the past decade, whereas in developed countries the proportion is more than 2 per cent.

On the other hand, Mexico's GNP has grown so fast that the monetary gains for science and technology have been huge. The annual increases in government spending on science and technology averaged 34 per cent in the decade 1971–81.

The present crisis has changed all this. Sitting in his modest cinderblock office, Rudomín says wistfully of the CONACYT

basic science budget, "This year it was going to be 400 million pesos. Unfortunately, we are going to have a change in the slope. Our concern now is to keep what we have achieved."

Whether that will be possible is an open question. The ambitious science programme — and the financial policies that have got Mexico into trouble were the work of the Portillo government. By custom, the new government of president-elect Hurtado will be able to reshape science policy entirely: political appointees such as Gollás are getting ready to leave their jobs. "Our programme in science and technology was oriented as far as possible to the goals of the national development programmes, the whole national economy and society. That connection should be maintained, Gollás says.

Rudomín met Hurtado in August and is on a committee of scientists appointed to advise the new president before he takes office on 1 December. "When there's an economic crisis, they will try to solve the immediate problems," Rudomín says. "I think it depends a lot on us, whether we will be able to convince them that it is important to have this [science]. I think that it's going to be a difficult task."

Woods Hole laboratory

Summer camp seeks more funds

Woods Hole, Massachusetts

The passage of Labor Day last Monday will allow the biologists' favourite summer camp, the Marine Biological Laboratory, to settle down to its year-round pre-occupation: fund-raising. By the centenary of the laboratory in 1988, the plan is to have raised \$27 million, much of which will be spent on the rehabilitation of laboratories. There are also fond hopes of augmenting the endowment fund, now more or less a pittance at just over \$3 million.

From candle-making to administration

According to Dr Paul R. Gross, director of the laboratory since 1978, money began to dry up in the early 1970s. One of the painful discoveries since then is that the laboratory has no funds with which to cover the cost of maintaining buildings, but there are also ambitions to get rid of wet laboratories immediately above parts of the library (which needs also to be extended by 10,000 square feet) and to rehabilitate the housing in which the

summer campers camp.

These anxieties seem not to have depressed this summer's visitors, more than 1,000 altogether. Clam chowder has been bounteously consumed. People have acquired a tan that should last until Thanksgiving, and the beaches have been as full as ever in the afternoons, at least until the weather turned cold towards the end of August.

The popularity of Woods Hole may be, in the long run, its most enduring asset. Gross says that the competition for places on the seven summer student courses has been as brisk this year as in the past. Three-quarters of the successful applicants turn out to be graduate students; the remainder are an interesting mixture of advanced undergraduates and postdoctoral people.

The competition from more senior people to spend the summer at the bottom right-hand corner of Cape Cod is probably, however, more influential. Some senior people turn up to help teach courses; others move their research projects lock-stock-and-barrel, bringing their assistants with them. Prudent applications to grant-making agencies specify the importance of access to fresh squid or some such animal, for the laboratory will charge bench-fees, while the cost of accommodation will be extra.

Woods Hole, a frankly elitist establishment, is thus a continuation of academic life by other means — means by which a person's knowledge of how to organize a

clam-bake or to sail a boat may partly offset his ignorance of, say, the mechanisms by which nuclear RNA is processed. Some regular summer visitors have opted out, saying that they prefer their vacations straight. The regulars remark on the importance of each evening's social encounters.

Financially, the seasonality of Woods Hole must be a serious handicap, which is why some importance is attached to two recent innovations — student courses in January (this year there were four) and the continuing research programme (which at present keeps 95 professionals active all year round). Even so, the laboratory (whose operating budget is just over \$6 million, excluding the cost of peripatetic research projects) reckons that it recovers only 42 per cent of the cost of its facilities from those who use them, and that it is at present running on a deficit of about \$750,000 a year.

Part of the problem is constitutional. Since it was established in 1888 to help young women from Boston learn some science, the laboratory has been managed by its members, of whom there are more than 650, who in turn elect the 36-member board of trustees which for practical purposes determines policy.

The climate of opinion seems slow to change (and remains unwilling to commit too much of the site to year-round activities). Indeed, Paul Gross calls himself a "one-man glue-pot" whose job is to hold the place together. Two tangible proofs of

Paul R. Gross — one-man gluepot

his success are apparent — reluctant agreement that there should be a fund-raising effort of any kind and the conversion of the candle-house left over from the New England whaling industry into a handsome administration building.

The plight of the laboratory is thus desperate but not serious. (People tend quickly to say that the Oceanographic Institute, split off from the laboratory in 1930, has greater difficulties.) Visitors nevertheless cannot help but wonder whether the first word in the laboratory's title is still apt, given that "marine" featured in the title of only one of this summer's seven courses.

Biotechnology index

Biotechnology beats bull market

Reflecting the US stock market's sudden surge in August, *Nature's* monthly index of biotechnology company stocks jumped 18.1 per cent from the base of 100 at which it began last June (*Nature* 12 August, p.599).

The *Nature* Biotechnology Index at the close of August (see box) shows that biotechnology companies outperformed two leading indicators of overall US industrial performance during the same period. The 18 per cent rise between 25 June and 27 August was greater than either the rise in the Dow Jones Industrial Average, which rose 10 per cent, or the rise in the Standard & Poor 400 Index which rose 7 per cent, as the table shows.

Biotechnology and other US stocks

Date	<i>Nature</i> Biotechnology Index	Dow Jones Industrial Average	Standard & Poor's 400 Index
25 June	100.0	803.8	122.09
30 July	102.7	808.6	119.95
27 August	118.1	883.47	130.75

Both of these general industrial indicators declined in July, whereas the Biotechnology Index rose to 102.7 in July.

The biotechnology companies as a group also did better than Standard & Poor's index of 12 leading US drug companies, which rose by only 3 per cent during the same two-month period. However, the drug index rose 11 per cent between the end of July and the end of August.

The *Nature* Biotechnology Index is weighted according to the total market value of each company's outstanding shares. It includes 15 representative biotechnology companies publicly traded in the United States. Three of the companies

are based outside the United States.

Wall Street analysts who follow the emerging biotechnology industry were not surprised that the companies as a group performed well during the sudden rally at the end of August that saw trading at record volumes. "People had been looking for refuges in this market" said one analyst at Oppenheimer and Company. "They were looking for safe stocks, buying defensively, selecting only stocks that looked like they would have high growth". More traditional US companies, in the steel, automobile and chemical industries, are unlikely to be favoured until traders think that the decline in interest rates will enable those ailing industries to recover, she said.

Among the biotechnology stocks listed in the *Nature* index, the best performance was by well-established firms, such as A/B Fortia of Sweden, Novo Industri of Denmark, and Genentech of south San Francisco, California. But the stocks of many of the smaller companies did not move at all and some declined. Analysts explained this by saying that active traders tend to avoid very small companies because a purchase can control the overall price. The fortunes of the smaller companies are affected by internal changes.

For example, Bio Logicals, of Ottawa, Canada, saw the value of its 5.9 million shares of outstanding stock decline from \$3 to \$2 per share between July and August, partly perhaps because it has been without a chief executive officer since Robert Bender left in May. Such changes make a big difference to a small company's owners, but little to the market as a whole. "It's a volatile market", as one Wall Street analyst said.

Deborah Shapley

Nature index of biotechnology stocks

1982 high	1982 low	Company (Headquarters)	Close previous month	Close 27 Aug	Change

CORRESPONDENCE

On dotty letters

SIR — It gives your readers, I suppose, some light relief when you publish dotty letters on improbable ways of achieving peace in our time. Grey Dimond's letter (*Nature* 15 July, p.220) on the merits of an exchange of marriageable young men and women in attractive uniforms between the Soviet Union and the West has, however, a sound basis despite the more fantastic embellishments.

In the past three years or so, roughly the period since the Soviet invasion of Afghanistan and the intensification of the cold war, the numbers of people visiting the Soviet Union from the United Kingdom have increased. So too have the numbers of Soviet citizens visiting Britain — largely in parties of 500 to 700 on cruise ships and staying for only three or four days. Though the British government signs every two years an agreement with the Soviet Union which includes a commitment to facilitate cultural, scientific and educational exchange, it sometimes obstructs exchange, and paradoxically this has been happening just when it is most needed. In addition to the severe restrictions on Soviet citizens wishing to travel abroad, those who manage to obtain external passports often have much difficulty in getting UK entry visas. Travel in either direction may also have been restricted by cutting to about half by a British government body early last year of the number of flights permitted each week between the United Kingdom and the Soviet Union — primarily for commercial reasons.

Exchanges are vital precisely because of our differences with the Soviet Union. Whether the aim of a visit be business, scientific exchange, tourism, diplomacy or nuclear disarmament, there is bound to be an educational aspect, an adjustment on either side, however slight, of perceptions and understanding of the cold war enemy, and this can only be for the good.

Japanese IQ

SIR — Regarding possible causes of Japanese children showing a significantly higher IQ than their US and European counterparts, Magyar (*Nature* 17 June, p.532) suggested that exposure to written Japanese might play a role. I should like to point out, however, that the spoken rather than the written form of Japanese language has been found to be responsible for a characteristic, epigenetic lateralization of auditory processing in the two cerebral hemispheres of native Japanese-speakers regardless of the ethnic identity^{1,2} (but do not be misled by ref.3 based on a complete misunderstanding of the subject). In this respect, both Koreans and Chinese exhibit the same type of lateralization as do Europeans whereas the Japanese and Polynesians belong to a minor group with a different type of lateralization. A hypothesis attempting to relate IQ differences to the first language spoken during childhood could be tested with populations in Taiwan and South Korea — both of which have recently experienced remarkable leaps in economic growth.

Bhargava (*Nature* 1 July, p.8), on the other hand, suspects that a quick democratization of

education accompanying economic improvement may have been responsible for the very high IQ of Japanese children. However, literacy among the Japanese had perhaps attained a level of 45 per cent for the male and 15 per cent for the female population by the mid-nineteenth century, and at the beginning of the twentieth century practically all children in Japan were attending primary school⁴. This would indicate that the Japanese were not very much behind the Europeans in terms of literacy, and that democratization of education in Japan was neither rapid nor very recent, as suspected by Bhargava. After the war, however, competition among the young Japanese for opportunities of higher education was very much intensified. Competition now starts very early — even at the entrance examination for "elite" kindergartens which will facilitate later competition for higher education in "good" universities promising a good income and a career of life-long commitment. It is therefore conceivable that fierce competition rather than democratization in education is a more likely cause of the higher IQ among Japanese children. The IQ of Japanese children who have attended, for a number of years, Japanese schools overseas (as in London or Sydney) — and in an atmosphere much less competitive than that in Japan — could well be used to test the point.

Disarmament ideas

SIR — Among the many documents presented to the UN General Assembly at its Second Special Session on Disarmament (7 June–10 July) was one from the Medical Association for Prevention of War (MAWP) containing a completely new proposal. This calls for "a comprehensive ban on all methods and means of warfare specifically designed to kill or injure by inducing human disease, as distinct from causing mechanical and/or thermal effects". The starting point for the proposal is not the usual one of weapon-types, but the type of effect of weapons on people. The distinction between disease-inducing and mechanical or thermal effects has to be defined for the disarmament diplomats. This can be done in terms of pathology and, in lay terms, by the contrast of disease-inducing for living things only with the similarities of mechanical and thermal effects on animate and inanimate.

The MAPW proposal builds on existing agreements and negotiations on chemical, biological and toxin, and "radiological" weapons; and on agreed prohibitions on the release of "dangerous forces" from nuclear electrical generating stations, the use of environmental modification techniques for hostile purposes, and the use of conventional weapons that leave fragments in the body which are undetectable by X rays (so hindering their surgical removal and hence enhancing the risk of infection). The proposed comprehensive ban would close loopholes in

the existing agreements and extend the range of prohibitions — notably by including "neutron" weapons.

Moreover, the proposal opens up a new approach to the question of a comprehensive disarmament programme. The established approach is across-the-board disarmament of all varieties of military power. Modern versions (the United States' and the Soviet draft programmes of 1962 and the draft programme considered by the Special Session) envisage across-the-board comprehensive disarmament in three stages. This is like eating a cake in layers, and it is a proven failure.

The MAPW approach is like eating a mango. The whole of the skin ("disease-making") is peeled off first. Successive bites or cuts into the fruit can be flexible in position, size and depth. A comprehensive ban on thermal attacks on people might follow naturally from the ban on "disease-making". (If it is impermissible to inflict disease on one's enemies, one also ought not to burn them.) Reduction in the global total of the nuclear arsenals to below the theoretical level that poses a threat of species' genocide might be the next step. A prohibition on the development of any new weapons of mass destruction should be achieved without difficulty, as discussions on this subject are already in progress. Complete nuclear disarmament might have to await the introduction of objective principles for fixing ceilings on military manpower and expenditure. Current implications are that these should be proportional respectively to population size and gross national product (GNP). MAPW has found that this would have little overall effect on the present global maldistributions, which could be considerably improved, however, if the maximum permitted levels of military manpower and expenditure were made proportional to the *square roots* of populations and GNPs respectively.

The MAPW approach to comprehensive disarmament does not aspire to the ultimate UN objective of "general and complete disarmament". It leaves behind a hard core of national conventional military power. The hope must be that, having eaten the fruit, the world would decide that the only thing to do with the stone is to throw it away.

Units rule OK?

SIR — We view the recent letter by H.H. Rossi (*Nature* 22 July, p.320) with some disquiet. Are we witnessing the beginning of a trend towards the more widespread adoption of that Worrying Hardy Annual, The Nameless Or Unqualified Number In Today's Science (WHAT NO UNITS)?

While recognizing the practical value of bare figures for purely personal or even small group use, we believe that in all published work Units Nevertheless Incorporate Total Simplicity Regarding Unequivocal Literate Expressions Of Knowledge (UNITS RULE OK).

NEWS AND VIEWS

Kaposi's sarcoma: an oncologic looking glass

from Jerome E. Groopman and Michael S. Gottlieb

To paraphrase Lewis Carroll in *Alice in Wonderland*, Kaposi's sarcoma has become "curiouser and curiouser". It is unlikely that over a century ago when Dr Morris Kaposi¹ described patients with "multiple idiopathic pigmented sarcoma of skin" he would envision the disorder becoming an intriguing clinical puzzle that spans oncology, virology, epidemiology, public health, immunology and sexual behaviour. Indeed, the current epidemic of Kaposi's sarcoma and acquired immunodeficiency syndrome may provide important insights into the pathogenesis, prophylaxis and rational therapy of neoplasia.

In the spring of 1981 the Center for Disease Control (CDC) in Atlanta received the first of a number of reports of *Pneumocystis carinii* pneumonia occurring in young, previously healthy, homosexually-active men². Shortly thereafter, an unusual dermal malignancy, Kaposi's sarcoma (KS), was observed in similar hosts³. KS is a well recognized, rare endothelial neoplasm which generally occurs among elderly men of Mediterranean and Jewish ancestry. KS also occurs in an endemic form in certain areas of equatorial Africa. The common epidemiological link between Kaposi's sarcoma, opportunistic infection and the initial American cases was that of male homosexuality. The patients manifested a profound deficiency in cellular immunity, with anergy to recall antigens on skin testing, lymphopenia and a reversal of the normal ratio of helper to suppressor/cytotoxic T-lymphocytes^{4,5}. This ratio, although not specific for this disorder, has become a marker for the acquired immunodeficiency syndrome (AIDS). As of August 1982, there are over 500 documented cases of acquired immunodeficiency syndrome and/or Kaposi's sarcoma. There have been over 175 deaths due to this syndrome since its recognition, and the epidemic appears to be spreading⁶. In January 1982 about one case per day was reported to the CDC, since January 1982, two to three cases per day are being reported. It is estimated that KS and AIDS will account for 2-3 per cent of all deaths among men 25-40 years old in New York City, Los Angeles and San Francisco. There are now well documented cases occurring in 27 states in the United States as

well as 8 foreign countries. Ninety-five per cent of the affected persons are men, 85 per cent are either homosexual or bisexual although recently there has been an increased incidence among heterosexuals. The groups at risk for the development of Kaposi's sarcoma and AIDS now include homosexually-active men, intravenous drug users, female prostitutes, Haitian immigrants to the United States, and most recently, adult male haemophiliacs. There have been several intriguing epidemiological studies conducted by the CDC. In Los Angeles, 9 of 13 cases studied over the past year had had contact with another person who either had or later developed AIDS. It is of note that no lesbians have developed the syndrome to date. Fifty per cent of the cases come from the New York metropolitan area, about 25 per cent from California and about 7 per cent from Miami. The increasing incidence of the epidemic and its apparent transmission by sexual contact, drug apparatus and blood products strongly suggest a viral agent. Although use of various 'recreational drugs', particularly amyl and butyl nitrate, was initially believed to be important in immunodeficiency, this is now unlikely as many individuals with AIDS/KS have never used such drugs. There may be a genetic predisposition to the syndrome, as about 50 per cent of homosexually-active men in the New York area who developed Kaposi's sarcoma were positive for HLA-DR 5, nonetheless, the syndrome has clearly occurred among genetically, ethnically and socially diverse groups. Of greatest concern is the significant morbidity and mortality of the disease. Approximately 40 per cent of patients die per year with AIDS/KS, nearly 70 per cent of the patients who developed the syndrome in 1980 have died.

In the light of the occurrence of AIDS among adult male haemophiliacs, the United States government is now studying the donation and processing of blood products including hepatitis B immunoglobulin, factor VIII concentrates, cytomegalovirus (CMV) immunoglobulin,

and the new hepatitis B vaccine, all of which are frequently obtained from homosexually-active men. Recommendations from the Federal Drug Administration and the Bureau of Biologics are expected shortly.

The dimensions of this epidemic and the number of individuals at risk are unknown. Homosexually-active men who are asymptomatic have been studied and found to have a helper to suppressor-T cell ratio intermediate between that of homosexual controls and homosexually-active men with AIDS. How many of these asymptomatic men will go on to develop AIDS and/or Kaposi's sarcoma is not known. Nor is it known how the epidemic can be contained, aside from avoiding intravenous drugs and perhaps promiscuous sex. Recommendations to homosexually-active men concerning their sexual practices are difficult for the practising physician and involve complex ethical and civil rights issues.

Clinically, the opportunistic infections seen in men with AIDS are quite varied. Certain protozoa, such as *Cryptosporidium* and *Isospora*, have caused severe diarrhoeal syndromes, these are generally pathogens in livestock. In addition, certain atypical mycobacteria have caused not only severe, fatal pneumonias but a miliary pattern. Fatal fungal infections, particularly *Candida* and *Cryptococcus*, disseminated viral infections with herpes simplex, varicella zoster and adenovirus, as well as infection with toxoplasmosis, *Pneumocystis carinii* and *Legionella* have all been seen in AIDS. Therapy for many of these viral, protozoal and atypical mycobacterial infections is poor and most hosts quickly succumb.

Previous studies of endemic Kaposi's sarcoma in equatorial Africa have associated development of the neoplasm with cytomegalovirus infection⁷. A number of hypotheses have been advanced correlating the development of Kaposi's sarcoma with acquired immune deficiency syndrome. Repeated cytomegalovirus infection among homosexually-active men may 'wear down' the immune system and lead to cellular immunodeficiency. Yet why did this become apparent only during the past 2-3 years? Is there a new strain of cytomegalovirus? Although this is

Jerome E. Groopman is in the Division of Hematology-Oncology and Michael S. Gottlieb is in the Division of Clinical Immunology - Allergy, UCLA School of Medicine, Center for the Health Sciences, Los Angeles, Ca 90024

possible, preliminary studies on CMV isolates from affected hosts have not been particularly revealing. Is there a new virus? The CDC is in the process of processing sera and tissue from affected hosts and introducing filtrates into animals. Short of this, it would be difficult to identify a new virus. Because of the outbreak of AIDS among Haitian immigrants, attention has recently been turned to the Caribbean. There is preliminary information that AIDS and KS may be occurring in an epidemic fashion in Haiti. Because the

human T-cell leukaemia virus has a tropism for helper inducer T-lymphocytes and because this retrovirus is endemic in the Caribbean, AIDS patients are being studied for HTLV by Robert Gallo of the NCI.

Additionally, Burkitt's lymphoma, cloacogenic carcinoma of the rectum and immunoblastic sarcoma appear to be occurring among American homosexual men at an increased frequency. Each of these cancers has been associated with DNA viruses of the herpes family. The epidemic of AIDS and KS affords a unique opportunity to study the relationship between immune status and the pathogenesis of certain forms of neoplasia. Considering the striking mortality, clues to aetiology that lead to rational therapy are needed. □

The geoid and geodynamics

from Bradford H. Hager

THE direct radar measurements of sea surface height from satellite GEOS 3 reported in this issue of *Nature* (p 117) by Ki-Iti Horai show that it is now possible to measure small changes in the shape of the geoid — the equipotential surface corresponding to mean sea level — with an accuracy of ± 50 cm. Detailed maps of geoid elevation with contours spaced as close as 1 m can thus be produced (see Fig 1a, p 118) and clearly show the effect of tectonic features such as deep sea trenches, outer arc rises, and oceanic ridges and troughs on the height of the geoid.

Variations in the height of the geoid are caused by horizontal variations in the density structure of the Earth. Early interpreters, assuming a rigid Earth, used the observed fluctuations of the geoid to bound the size and depth of the density contrasts that brought them about. Constraints were thus placed on the (supposed finite) strength of the Earth¹. Now, observations of the postglacial rebound and plate motions make it clear that the Earth interior behaves as a fluid, not a rigid material, over geological time, requiring interpretation of geoid anomalies in a dynamic system²⁻⁴. As is well seen in Horai's paper, the study and interpretation of the figure of the Earth is now moving from the static domain of physical geodesy to the domain of geodynamics.

Analysis of geoid anomalies in terms of density contrasts has always been hindered by the lack of a unique interpretation — an infinite family of distributions of density contrasts within a given body can satisfy

any observed gravitational potentials outside that body. Adding the extra constraint that the equations of motion in the fluid interior of the Earth must be satisfied has only recently been exploited in interpretation of the Earth's gravity field, but imposes a limit on the class of acceptable solutions.

The basic physics of the problem are relatively simple, but contain some subtleties. Consider a density contrast of spherical harmonic degree l placed at a radius r in a fluid mantle. The gravitational potential at the surface ($r = r_c$) is reduced by a factor $(r/r_c)^{l+2}$. The density contrast causes flow which leads to a downward deflection of the surface of the Earth above high density regions and upward deflection above low density regions. Trenches and oceanic ridges are the directly observable result of this type of deflection. Similar deflections occur at the core-mantle boundary and at any other internal layer boundaries which might exist. (Settling the controversial question of the existence of these boundaries⁵⁻⁷ may soon be possible using the techniques outlined here.) Solving the equations of motion within a fluid mantle⁸ shows that the deflection of the surface of the Earth is also approximately given as $(r/r_c)^{l+2}$. The gravitational effects of the surface deformation and the driving density contrast are of comparable magnitude and opposite sign and nearly cancel.

The gravitational field of the Earth thus provides the most sensitive of all experiments, the null experiment, where the net result is a small number determined by the difference of two large effects. The sign of the result depends on which of the effects is dominant.

As an example, consider the geoidal

signal resulting from the subduction of a cold, dense slab of lithosphere. If most of the stress from the sinking slab were directly transmitted to the outer surface of the Earth, the gravitational effect of surface deformation would be of greater magnitude than that from the slab itself, resulting in a net negative geoid anomaly. If the stress were transmitted more efficiently to a discontinuity deeper in the mantle, the dense slab, being closer to the surface, would dominate the gravity field, leading to a positive geoid anomaly.

Horai's geoid map shows that except for the localized area comprising the trench, the gravitational attraction of the slab is larger than that of the deformed upper surface. This shows that the weight of the slab is carried mostly by support from below such as would be provided by an increase of viscosity with depth or by the presence of a chemically induced density contrast between the upper and lower mantle. Fault plane solutions showing in general down dip compression in deep slabs are consistent with either of these interpretations⁹. An increase in effective viscosity with depth might be the result of stress-dependent rheology, as Horai suggests, or of the competing effects of increased pressure and temperature on rheology.

Many of the features of the global geoid are associated with subduction zones¹⁰, but there are many features such as the geoid lows over Siberia, Hudson Bay, and the Ross Sea, and the high over Africa, not associated with subduction. In these areas, we have no *a priori* knowledge of the sign of the causative density contrasts. They may well be the result of density contrasts not associated with present plate motions¹¹. In particular, Anderson¹² has recently suggested that the geoid highs correspond to anomalously hot mantle, with geoid lows corresponding to colder mantle. This scenario is plausible if in these regions the gravitational effects of surface deformation are large, consistent with efficient coupling of stresses to the upper surface.

How can such a hypothesis be tested? It is not possible to measure directly density contrasts in the interior of the Earth, but it is possible to measure deformation of the outer surface. The ratio of geoid height to

surface deformation is observable and very sensitive to the distribution of viscosity^{3,8} as well as to the depth of the convecting layer. The fact that Africa (geoid high) is on average 500 m higher than Siberia or the area around Hudson Bay (geoid lows) supports the hypothesis that the geoid in these regions results from less dense and more dense mantle respectively, with stresses transmitted efficiently to the surface of the Earth. This would be consistent with the absence of a low viscosity asthenosphere in these regions. This absence would not be surprising as these areas are ancient cratons.

McKenzie and others¹³ have looked at correlations between bathymetry, interpreted as surface deformation, and geoid anomalies on a smaller scale, these anomalies are consistent with those obtained for calculations of convection in a uniform viscosity fluid. Given the sensitivity of geoid anomalies to viscosity structure, it would be of great interest to extend the calculations to include the low viscosity asthenosphere generally supposed

to exist beneath oceanic plates to see if the geoid observations are in accord with this type of rheology.

Seismology provides additional constraints. Density and seismic velocity are, in general, positively correlated¹⁴. At present, seismologists are making rapid progress in deciphering the three-dimensional distribution of lateral heterogeneities in seismic velocity in the Earth's interior¹⁵.

We are at the beginning of an exciting era in geodynamics. High quality geoid observations, combined with high quality determinations of surface deformation and new high resolution seismic data will provide powerful constraints which must be satisfied by the next generation of geodynamic models. Combining all three data sets will decrease the non-uniqueness inherent in each. The physics of the gravity field, which makes it effectively a null measurement, should make it possible in the near future to constrain variations in mantle rheology and the depth and scale of mantle convection. □

template. The sigma subunit is lost and the resulting ternary or elongation complex moves along the DNA simultaneously synthesizing the RNA transcript, which is continuously displaced from the coding DNA strand.

DNA unwinding by RNA polymerase was first unequivocally demonstrated for open promoter complexes by Wang and co-workers^{3,4}. These studies pioneered the approach of measuring DNA unwinding from the difference in linking number between DNA samples obtained by sealing a nicked circular duplex DNA with DNA ligase, in the presence and absence of the DNA binding protein⁴. Gamper and Hearst have now measured and compared DNA unwinding induced by RNA polymerase in binary, initiation and elongation complexes formed at a single prokaryotic promoter sequence in simian virus 40 DNA¹. They used gel electrophoresis to measure the change in the linking number of closed circular SV40 DNA in transcriptional complexes in which the DNA had been relaxed using a DNA nicking-closing extract. This procedure removes the overwound DNA turns arising from protein binding, thereby fixing the topological change.

The degree of DNA unwinding was found to be the same for all three transcriptional complexes and, for the elongation complex, was independent of its sequence location on DNA. The extent of DNA untwisting was deduced to be 17 ± 1 base pairs ($580^\circ \pm 30^\circ$) per polymerase molecule. The result can be compared with a value of approximately seven base pairs previously reported by Wang for open promoter complexes⁴. Although these unwinding estimates are somewhat different, the important result established by the new study is that the extent of DNA unwinding is constant throughout transcription.

Invariance of the DNA unwinding angle as the ternary complex progresses along the DNA helix suggests that the size of the unwound DNA region is tightly controlled by polymerase and is independent of the DNA sequence in the complex. A topological model that accommodates this result has been proposed to describe elongation by polymerase (Figure 1). It is suggested that RNA polymerase has two windase activities that rigidly determine the limits of the DNA unwound region and which facilitate its movement along the DNA helix. The leading unwindase opens the DNA helix which is then subsequently reformed by the lagging rewindase. These activities are coupled and result in translocation of the enzyme relative to the substrate DNA and the RNA transcript. Given the size of polymerase and that of the transcript, it seems unlikely that the ternary complex itself rotates on DNA. A more plausible and topologically feasible solution is that the DNA on either side of the unwound region rotates about the helix axis (Figure 1). Because the helix axis

DNA unwinding in transcription and recombination

from L. Mark Fisher

LOCAL unwinding of the DNA helix plays an important role in many biological processes. In transcription, opening of the DNA helix by RNA polymerase allows access to the coding DNA strand and copying of the DNA message into an RNA transcript. The formation of heteroduplex DNA structures by recombination between homologous DNA molecules, catalysed by RecA (and other) proteins, must also involve unwinding of duplex DNA. Two recent papers reveal some intriguing features of DNA unwinding by *Escherichia coli* RNA polymerase¹ and RecA protein² (see this issue of *Nature*, p 185).

DNA helix unwinding may most conveniently be investigated by taking advantage of the topological properties of circular DNA. A closed circular duplex DNA is characterized by a topological parameter termed the 'linking number', which specifies the number of times the two complementary DNA strands are intertwined in the DNA circle. The linking number is an invariant and can be changed only by breaking and resealing the DNA. Therefore, if protein binding induces unwinding in one part of the helix in a closed duplex DNA circle, this must necessarily be accompanied by overwinding of the DNA elsewhere in the DNA molecule. The recent studies on unwinding by RecA protein and

by RNA polymerase have in different ways both exploited this phenomenon.

Unwinding by polymerase

RNA polymerase from *E. coli* is a pentameric complex of subunit structure $\alpha_2\beta\beta'\sigma$ and molecular weight 465,000. RNA synthesis by the enzyme proceeds via the sequential formation of four different enzyme-DNA complexes. The holoenzyme first binds at the promoter site forming the closed promoter complex, in which the enzyme is associated with DNA sequences in their helical conformation. This complex isomerizes, unwinding and separating the DNA strands to form the open promoter (binary) complex. Exposure of the coding DNA strand allows initiation of RNA synthesis to take place. The short RNA oligomer made in the initiation complex forms an RNA-DNA hybrid with the coding strand of the DNA

Fig. 1 Topological model for the RNA polymerase elongating complex (taken from ref 1). Filled triangles denote swivelase centres, the open triangle denotes the catalytic site for RNA synthesis. The unwound strands of the DNA are bound to polymerase, possibly to the β and β' subunits [Figure © M I T Press]

L. Mark Fisher is in the Department of Biophysics, King's College, University of London.

remains fixed, the proposed mechanism would not result in spatial revolution of the entire DNA molecule about polymerase during transcription of a circular DNA. Continuous displacement of the transcript from the DNA template is assumed to involve the rotation of the RNA-DNA hybrid. Further experimental work will be necessary to validate the details of the model and to examine its role in pausing and termination of RNA synthesis by polymerase.

Unwinding by RecA protein

The RecA protein is involved in DNA recombination and repair in *E. coli*. This 38,000 molecular weight protein has an ATP-dependent DNA strand transfer activity that promotes the formation of joint molecules between duplex DNA and either single DNA strands or double-stranded DNA with single-stranded gaps⁵. Whatever the precise mechanism of DNA strand transfer, the RecA protein must somehow unwind duplex DNA so as to catalyse the formation of heteroduplex DNA structures.

Several groups have shown that RecA protein binds cooperatively both to single-stranded and to duplex DNA⁶⁻¹¹. Complexes with duplex DNA are stabilized by the inclusion of ATPγS, a non-hydrolysable ATP analogue. These nucleoprotein complexes appear in the electron microscope as right-handed helical filaments in which the duplex DNA is elongated by about 50 per cent. This lengthening of the DNA is consistent with unwinding of the DNA helix on interaction with RecA protein¹². Stasiak and Di Capua (see p 185) have now focused on the ATPγS-stabilized cooperative binding of RecA protein to closed circular duplex DNA². Local unwinding of this DNA by RecA protein induces a compensating overwinding (positive supercoiling) of the DNA segment not complexed with protein. The countervailing positive supercoiling of the DNA constrains the extent of protein-DNA complex formation.

The amount of RecA protein that binds to DNA depends on the negative superhelical density of the starting circular DNA. Clearly, the higher the initial negative supercoiling (underwinding) of the DNA, the more protein can bind before the binding constraint is reached. Stasiak and Di Capua used electron microscopy to

measure the fraction of the DNA circle covered by protein when negatively supercoiled DNA samples with different mean linking numbers were incubated with excess RecA protein. By extrapolation, they were able to estimate the linking number of the DNA in a closed duplex circle completely covered with RecA protein. The linking number they obtained had essentially the same value as the number of visible helical turns counted for the nicked DNA molecule fully covered with the RecA protein. These elegant studies show that the DNA helix in the complex follows the protein helix seen in the electron microscope and that RecA protein unwinds the DNA helix from the usual value of about 10.5 base pairs per turn to 18.6 base pairs per turn. Studies by Shibata's group, described in *Nature* last week (299, 86), have shown that relaxation of RecA protein — closed

circular DNA complexes by a nicking-closing extract generates highly negatively supercoiled molecules consistent with RecA mediated unwinding of the DNA.

Intercalation of protein (or conceivably ATPγS) into the DNA helix could account for DNA unwinding in DNA-RecA protein filaments. Alternatively, the helix may be melted with complementary DNA strands separated and not base paired. Interestingly, RecA protein can itself form filamentous helical aggregates similar to those observed with DNA⁸. It seems possible, therefore, that the RecA protein filament provides a rigid framework to which the DNA is constrained to bind in an unwound conformation. The precise nature of RecA protein-DNA interactions in the filaments and the relevance of these structures in recombination await biochemical analysis. □

Murine models of multiple sclerosis

from Peter Doherty and Elizabeth Simpson

MULTIPLE SCLEROSIS is a chronic progressive debilitating disease which remains an intractable human problem. Despite many years of research there is no very clear indication as to aetiology, although a number of candidate viruses have been proposed. There is a tendency for people who develop multiple sclerosis (MS) early to have had several infections in childhood. There are also marked geographical variations, with the disease increasing in incidence with distance from the equator. Another clue is provided from HLA-typing studies which show a preponderance of HLA, A2, B7, DRW2 in MS patients from North America and northern Europe, but superimposed on this there is a Gm allotype linkage, an interesting finding in view of recent reports of Gm allotype- and HLA-linked control in autoimmune disease (Whittingham *et al Clin exp Immun* 43, 80, 1981, Uno *et al Nature* 292, 768, 1981).

Experimental analysis has been hampered by the lack of a generally acceptable animal model. Over the past twenty years much work has been done with the acute form of experimental allergic encephalomyelitis (EAE) although the recurrent progressive pattern of MS is not reproduced. A genetic component of EAE in rats and guinea pigs is indicated, however, since the induction of disease is dramatically strain dependent. It has also been established that EAE in these species can be induced by different fragments of myelin basic protein (MBP), and that the induction of both effector and suppressor T-cell subsets can

be separated by manipulation of the immunization schedule. A further substantial advance has been the development of experimentally induced relapsing EAE, first in rats and guinea pigs, and more recently in mice, which allows more detailed genetic and immunological analysis.

Over the same period that studies on relapsing EAE have developed, other research groups have been working on virus-induced primary demyelinating processes in mice. A recent meeting* provided a timely opportunity to bring together those studying autoimmunity and virus-induced demyelination with people concerned with analysis of basic immune mechanisms and T-cell circuits in mice.

It is apparent that the relapsing EAE model in the mouse and the chronic disease process caused by some viruses such as Theiler's virus (a picornavirus) have many features which mimic the pathology of human MS. However, there are also a number of differences. The progress of relapsing EAE is not inexorable, and substantial recovery with re-myelination commonly occurs whilst it is scarcely ever seen in humans. In progressive virus models, small amounts of virus antigen persist (H. Lipton, Northwestern University Medical School, Chicago) whereas attempts to recover viruses or detect virus coding sequences that are present in MS but absent in normal human brain have never been consistently successful. Even so, the similarities are sufficient to warrant thorough analysis of cellular

immune regulation and effector function in affected animals. In fact, the main virtue of the meeting may have been in indicating that common pathways exist in the development of these apparently aetiologically unrelated models.

The influence of genetic factors is seen very clearly in both virally induced demyelinating disease and EAE mice. The SJL mouse, known to have both lymphoproliferative and autoimmune tendencies, is extremely sensitive to induction of demyelinating disease. However, a propensity to autoimmunity, itself multigenic, (A. Steinberg, NIH, A. Theofilopoulos, Scripps Foundation) is not responsible *per se*, since NZB and other autoimmune strains are not highly susceptible to EAE. The induction and expression of acute EAE in mouse is under the control of both H-2 and non-H-2 genes. Involvement of H-2 Ir genes is indicated by the effects of treating developing EAE with anti-Ia antisera (L. Steinman, Stanford University School of Medicine). Analysis of a set of recombinant inbred strains shows that one of the non-H-2 genes may be controlling a histamine receptor sensitivity to histamine release and thus susceptibility to rapid extravasation of fluid and cells in the central nervous system (CNS) of mice sensitized to MBP (D. Linthicum, USC Medical School, Los Angeles). Detailed studies of the susceptibility of relapsing EAE to a variety of mouse strains reveals that the disease may be induced in many strains other than STL but that the MBP fragment responsible varies from strain to strain (R. Fritz, Emory University). The absolute requirement for T cells is shown by the inability to induce the disease in SJL/hr⁻ mice, which lack a thymus.

The meeting also raised intriguing points about the nature of the pathological process of CNS damage itself. It is clear that the acute autoimmune disease at least is T cell mediated and seems to be caused principally by the Ly 1⁺ class of effector cells. This is not established for the virus models, but there is obviously an immune component. However, both sorts of experimental systems show instances in which the oligodendrocytes that synthesize the myelin remain intact and there is little evidence of neuronal death or axonal degeneration. Conventional immunological wisdom would have us believe that Ly 1⁺, Ia-restricted T cells are the instigators of demyelinating damage, but there is no evidence that Ia antigens are present on myelin, and previous claims that such determinants are present on the surface of oligodendrocytes do not seem to be generally accepted. Also, morphological evidence would suggest that cellular damage to the myelin sheath is a function of monocytes/macrophages rather than T cells. How then do T cells induce demyelination? Does this mean that the T-cell effect must be operating through a short-range product such as a lymphokine, lympho-

toxin or prostaglandin? As Cantor pointed out, Ly 1⁺ T cells can kill by activating macrophages to produce peroxidase, which then kills both macrophage and the Ly 1⁺ inducer T cell.

We may thus be looking at a final common pathway where persistent antigen in brain, whether virus, MBP or some other CNS component, is recognized on the surface of Ia-positive antigen-presenting cells (derived from invading monocytes) and where the demyelinating process itself is a bystander effect reflecting secreted products from the macrophage-lymphocyte interaction causing a physiological defect in oligodendrocyte function, or direct damage to the myelin sheath. If this analysis is correct, then MS could be a disease of multiple aetiology, with a common pathological process. One point that might make us doubt this possibility is that there are apparent Ir gene effects which may indicate the involvement of a single pathogen. However, this could equally reflect a common neurological sensitizing component regardless of the triggering.

What of the future? It seems that we now have reasonable murine models for investigating chronic demyelinating disease in the context of contemporary immunological and molecular biological concepts and

techniques. A clear understanding of suppressor and effector circuits in both the virus and EAE models can readily be developed. The possibility that non-MHC-restricted suppressor molecules from antigen-specific clones may be targeted onto relevant cell sets, as suggested by Cantor, can be analysed. A search can be made to see whether infection with various viruses causes development of brain-specific T and/or B cell populations using cloning and hybridoma techniques. This approach has been effective in the murine reovirus diabetes model (M. Haspel, NIH).

Do viruses trigger MS? Certainly the mild pleocytosis that is a common feature of many childhood infections should allow exposure of CNS components to immunologically competent cells which are non-specifically drawn into the CNS during mild inflammatory processes. We should, over the next 10 years, get the answer for one candidate virus, measles, since 90 per cent of children in the United States are given live vaccine at an early age and measles has virtually disappeared. In contrast, in the United Kingdom only about 15 per cent of children are vaccinated against measles. However, in the absence of any correlation between measles and MS there is ample scope for experimental analysis which has some hope of relevance.

Haemocyanins to haemerythrins

from E F J van Bruggen

THE invertebrate respiratory proteins include the blue, copper-containing haemocyanins of molluscs and arthropods, the haemoglobins (or erythrocruorins) from a variety of invertebrates, and the burgundy-coloured, non-haem iron haemerythrins of certain sipunculid worms. Although all have a common function — oxygen transport in the blood — they are typically giant molecules which show a beautiful but bewildering range of architectures. Because the molecules are so large many important findings come from electron microscopy. Unfortunately, extensive subunit heterogeneity has hitherto prevented detailed X-ray crystallography and sequencing. These problems are gradually being overcome, and a workshop was held in Leeds University* at which recent findings were discussed.

Arthropod haemocyanins have polypeptide subunits of molecular weight 70,000 which aggregate to form multimers containing up to 48 subunits. Three groups of workers reported extensive amino acid sequences of subunits of Cheliceratan

haemocyanin, those from horseshoe crab, *Tachyplesus* (T. Nemoto and T. Takagi, Tohoku University), *Limulus* (A. Riggs *et al.*, University of Texas), and scorpion, *Eurpelma* (B. Linzen *et al.*, University of Munich). All show extensive homologies, and are of particular interest in that all contain an unusual peptide, -His-His-Trp-His-Trp-His-, as part of their sequence, about 170 residues from the N-terminus. It seems probable that this forms a major part of the copper-containing active site. Nemoto's group reported 359 residues of the N-terminal sequence and about 100 residues of the C-terminal sequence, leaving about 100 residues to be sequenced.

It will be of great interest to correlate these data with the X-ray studies that are now coming to fruition. Thus, the X-ray structure of spiny lobster (*Panulirus interruptus*) haemocyanin at 4 Å resolution not only showed the tertiary structure of the binuclear copper centre, but also enabled a very precise model to be made for the quaternary structure of this hexameric molecule (W. Gaykema *et al.*, Rijksuniversiteit, Groningen). The model should

*The workshop was held in the Biochemistry Department, University of Leeds 19-22 July 1982 and sponsored by the European Molecular Biology Organization.

E F J van Bruggen is in the Biochemistry Laboratory of the Rijksuniversiteit Groningen, Nijenborgh 16 9747 AG, Groningen.

help interpret the different view of multi-hexameric molecules obtained by aperiodic averaging of electron microscopic images in combination with correspondence analysis (M van Heel, Rijksuniversiteit, Groningen and J Frank, New York State Department of Health, Albany) Together with information from immunoelectron microscopy using polypeptide chain-specific Fab fragments, we now have a considerably improved model for the quaternary structure of the Cheliceratan haemocyanins and their dissociation products (J Lamy *et al*, University of Tours, B Linzen *et al*, University of Munich; E van Bruggen *et al*, Rijksuniversiteit, Groningen)

A great deal of chemical spectroscopy now confirms previous ideas that the coppers in the active site of haemocyanin are held by imidazole nitrogens (E Solomon, Stanford University) Interestingly, there are a number of similarities with another copper protein, *Neurospora* tyrosinase, and the enzymatic activities, known for many years to be exhibited by haemocyanins, were discussed following their re-investigation by several groups (A Nakahara, Osaka University)

Some progress has been made with the structures of the mollusc haemocyanins and the annelid haemoglobins For the

former, elegant work using proteases has confirmed the structure of the polypeptide in gastropod haemocyanins as containing eight linked oxygen-binding units in a polypeptide of molecular weight $> 400,000$ Cephalopod haemocyanins seem to be essentially the same (C Gielen and R Lontie, Katholieke Universiteit, Leuven) One of the functional units of *Helix pomatia* haemocyanin has now been crystallized Several models for annelid haemoglobins (molecular weight up to 4×10^6) were discussed Electron microscopy shows the molecule to be a stack of two hexagonal plates 26 nm across, but many problems remain to be resolved regarding the number of subunits, their haem content, and their arrangement in the molecule

A study of the various developmental stages of the crustacean (N Terwilliger, University of Oregon) gave the first indication that there may be a 'fetal haemocyanin' This is particularly interesting as there is evidence that the variety of polypeptides which form arthropod haemocyanin (for example 12–15 in *Limulus polyphemus*) are coded by a family of mRNA molecules The polypeptides produced appear to undergo few if any post-translational modifications (E Wood and K Siggins, University of Leeds) □

doubt that compounds within the iron-oxygen system can exhibit marked changes in chemical properties at the pressures and temperatures of the Earth's deep interior To what extent these changes could decrease the miscibility gap between Fe and FeO liquids is unknown

Ringwood's model for the core has been simultaneously provocative and vexing He invokes a metallization of FeO at high pressures, such that significant amounts of the oxide can dissolve into the iron-rich core However, the electronic-bonding properties of FeO are complex and not well understood⁵ it appears that theory (for example, quantum-mechanical band calculations) cannot help us here On the other hand, wüstite exhibits a rich defect chemistry, with the result that stoichiometric FeO has virtually never been synthesized Rather, the experimentalist must work with Fe_{1-x}O ($0 < x \leq 0.15$), and it is difficult to be sure that identical wüstite compositions are reproduced from one laboratory to another Hence, not even the zero-pressure, room-temperature properties of wüstite are well documented

The only data on Fe_{1-x}O at the conditions of the core result from shock-wave experiments⁶ Indeed, the equation-of-state measurements demonstrate that wüstite transforms from its initial state (ionically bonded, NaCl-like structure) at shock-pressures above 70 GPa According to these data, up to 45 mol per cent FeO (~ 10 wt % O) dissolved in Fe satisfies the observed density of the core However, neither the crystal structure nor the bonding character is determined in the shock experiments, and numerous interpretations of the transition in FeO are possible Various authors have favoured either crystal-structured or electronic (including magnetic) changes, or both⁶⁻⁹ A definitive answer could be provided by measurement of the electrical resistivity of wüstite at high pressures and temperatures One group¹⁰ has found no resistivity anomalies to over 100 GPa (estimated) at

Oxygen in the Earth's metallic core?

from Raymond Jeanloz

THE outer core of the Earth has the properties of a molten iron alloy Its density, however, is nearly ten per cent less than that of iron, and considerable effort has gone into determining the 'lighter component' that is alloyed with the iron The composition of the core is of particular geochemical interest, as it provides a constraint on models of the early history of the Earth But a major question has been to what extent can (or must) one invoke unusual chemical properties for material existing at the 130–330 GPa (1.3–3.3 Mbar) and $\sim 4,000$ – $6,000$ K pressures and temperatures of the core? Several investigators have recently emphasized the degree to which chemical behaviour may change at such extreme conditions, as compared with our experience with the same materials at low pressures and temperatures

At a time when sulphur was considered by many to be the most plausible candidate, Ringwood¹, reviving earlier speculations, argued forcefully that oxygen must be the light component within

the core This might appear strange at first After all, wüstite (ideally, $\text{Fe}^{2+}\text{O}^{2-}$) is an ionic solid, with the result that most compositions in the system Fe–FeO melt (at zero pressure) to an immiscible mixture of metallic (Fe-rich) and nonmetallic (FeO-rich) liquids Therefore, one would hardly expect significant amounts of FeO to dissolve preferentially out of the Earth's oxide mantle and into the metallic core In fact, experiments had already indicated that metallic iron separates out of an oxide phase at high pressures and temperatures²

where hpp indicates a high-pressure phase (structure uncertain) and ϵ is the hexagonal-close-packed phase of iron

We must note, however, that FeO becomes a semiconductor in the liquid state, and Ringwood's conclusion that iron and iron-oxide liquids become miscible at high temperatures ($\geq 4,000$ K) is consistent with the available data^{1,3} That Fe in an oxide undergoes an electronic transition at high pressures has recently been verified⁴ a high-spin \rightarrow low-spin transition occurs (with no change of crystal structure) at 55 GPa in Fe_2O_3 There is no longer much

room temperature. This result does not support Ringwood's metallization hypothesis, but the effects of high temperature and of melting on the bonding character of FeO remain unknown at the pressures of the core¹¹.

Another dimension to the behaviour of iron oxides at extreme conditions has recently been emphasized by Liu and co-workers, who propose that the effects of nonstoichiometry have been underestimated^{12,13}. Extrapolating from earlier results, these workers suggest that wüstite becomes less stoichiometric with increasing pressure

with x increasing to a value of 0.25 with pressure. Ironically, this brings us back to Mao's conclusion³ that equation (1) proceeds to the right (it is worth noting that the nonstoichiometry of wüstite is associated with microdomains of magnetite — Fe_3O_4 , or $\text{Fe}_{0.75}\text{O}$, containing both Fe^{2+} and Fe^{3+} — within the FeO structure). At face value, it would seem that this proposal works against Ringwood's hypothesis,

with Fe separating out of the oxide phase. Nevertheless, the concept that the defect density (that is, the nonstoichiometry) could increase with pressure invites further work (the existing data in support of this are not definitive).

The significance of defects lies in the control of the nonstoichiometry by oxidation-reduction conditions (that is, Fe^{2+} – Fe^{3+} equilibria). However, the oxygen fugacity can only be poorly determined in ultrahigh pressure-temperature experiments, at present, although every expectation is that this is an important variable^{2,12}. In fact, one of the major reasons for geochemical interest in the light component of the core is to better constrain the redox state of the Earth's mantle, especially during the early history of the planet. To date, much of the research in experimental geophysics has concentrated on the effects of high pressures upon mineral properties and equilibria. We are now seeing a trend emphasizing the additional influences of high temperatures and oxidation state on the chemistry of deep planetary interiors. □

of the processing enzymes

Detailed knowledge of poliovirus genome sequences may also contribute to the development of improved live virus vaccines, with genetic determinants optimized for antigenicity and stabilized for attenuation. An important step in this direction is the recent determination of the total genome sequence of the Sabin type 1 attenuated vaccine strain⁶. When compared with that of the parental Mahoney strain, the genome of the attenuated derivative contained 57 base substitutions (total genome = 7,441 nucleotides), 21 resulting in amino acid changes. Twelve of the missense mutations occurred in the capsid proteins and were largely clustered in VP1, raising the possibility that attenuation in part involved modification of the virion surface. Gene sequencing is underway for other poliovirus strains, and some preliminary sequence data for Sabin type 3 were presented.

Poliovaccine development may be aided by progress in developing synthetic vaccines for another picornavirus, foot-and-mouth disease virus (FMDV). Synthetic vaccines offer the advantages of stability, increased economy of production and minimal containment hazards. Two approaches, based on the findings that the purified FMDV VP1 induces protective antibodies⁷, are being explored. The first involves expression in bacteria of a cloned VP1 gene⁸. Initial results were encouraging but the first generation of products had a much lower level of immunogenicity than conventional FMDV vaccines. The second approach involves the chemical synthesis of peptides⁹ representing sequences from VP1. Such products, when linked to a protein carrier, were more immunogenic than an equivalent mass of VP1 and stimulated neutralizing antibody and protection against virus challenge in experimental animals¹⁰.

The limited evidence available also suggests a role for VP1 in poliovirus antigenicity, although the antigenic structure of polioviruses appears to be quite complex. Data were presented indicating that isolated poliovirus polypeptides (VP1, VP2 and VP3) were each able to induce low levels of neutralizing antibody in animals and to prime a recipient for the production of neutralizing antibody on subsequent immunization with small amounts of intact poliovirus (A. L. Van Wezel and P. Van der Marel, personal communication).

Among the biochemical methods of poliovirus strain identification, ribonuclease T₁-oligonucleotide mapping of viral RNAs^{11–13} is the current technique of choice. Vaccine-related isolates can generally be readily distinguished from wild strains. Oligonucleotide maps are highly reproducible, such that good agreement exists in results and interpretations when different laboratories examine the same isolates. The technique is

Poliomyelitis — epidemiology, molecular biology and immunology

from P. D. Minor, O. Kew and G. C. Schild

At a recent World Health Organization meeting the current status of poliomyelitis in the world was discussed together with recent progress in molecular biological and immunological approaches to the study of polioviruses. Precise methods for strain characterization of polioviruses were seen as essential for epidemiological purposes and studies of vaccine safety and efficacy.

Participants from several countries (China, Japan, UK, US, The Netherlands, Sweden, Switzerland and USSR) reviewed their epidemiological experiences of poliomyelitis during the past triennium. These presentations and a general international review from data reported to WHO showed that poliomyelitis, although well controlled by the use of vaccines in developed countries, remains a major problem in the developing world^{1,2}. Epidemics of poliomyelitis in unvaccinated populations are chiefly caused by type 1 poliovirus, but in countries with well established vaccination programmes where paralytic cases have been reduced to a very small number, some of the few cases reported are associated with the use of live attenuated virus vaccines, particularly in cases involving poliovirus types 2 and 3.

Current research on the characterization of polioviruses emphasizes the biochemical analysis of poliovirus genomes, and the comparison of the antigenic characters of different strains using monoclonal antibodies.

A major advance has been provided by the determination of the complete nucleotide and deduced polypeptide sequence of a type 1 poliovirus (P1/Mahoney/USA/41)^{3,4}. The virus genome encodes a single large polypeptide which is specifically cleaved to produce the viral capsid proteins (VP1, VP2, VP3, VP4) and several non-capsid proteins, including an RNA polymerase, a viral protease⁵ and other proteins of yet unknown function. Complete processing of the polypeptide seems to occur by the combined action of cellular and virus-encoded proteases. Three distinct dipeptide sites are cleaved during processing⁵. Gln-Gly pairs are cleaved by the virus-encoded protease, Tyr-Gly pairs are probably cleaved by a cellular protease, and an Asn-Ser pair in VP0 is cleaved to produce VP2 and VP4 by an unidentified protease during the final stages of virion morphogenesis. Knowledge of the activities and specificities of the virus-encoded protease may open the way for development of a rational chemotherapy for poliovirus (and other picornavirus) infections by the use of specific inhibitors.

P. D. Minor and G. C. Schild are in the Division of Virology, National Institute for Biological Standards, Holly Hill, Hampstead, London NW3, and O. Kew is in the Center for Disease Control, Atlanta, Georgia.

extremely sensitive in detecting minor genome variations between strains¹⁴. The tendency of polioviruses to undergo genome variation during natural infections (an excellent example of this was presented for a type 2 vaccine strain which underwent long-term replication in an immunodeficient child)¹⁵ limits the utility of this technique in detecting distant genetic relationships between strains. This same process imposes an extreme limitation on the value for strain identification of SDS-polyacrylamide gel electrophoresis of viral polypeptides. An alternative method was suggested involving restriction mapping of cDNA transcripts of viral RNA¹⁶. This approach is expected to be less sensitive than oligonucleotide mapping and consequently may reveal more distant relationships between strains which are not apparent from T₁ maps.

Several workers continue to use strain-specific absorbed sera¹⁷ for the identification of poliovirus isolates as vaccine-derived or 'wild' and this technique was considered practicable and reliable. In general, designation of isolates as vaccine-derived by this method agree well with the results of oligonucleotide mapping.

Methods of identifying strains using monoclonal antibodies were reported^{15, 18-23}. International collaborative studies, organized through WHO, to examine the value of strain-specific monoclonal antibodies in strain identification and to compare the results obtained with those obtained by oligonucleotide mapping were proposed and this project is in progress. Preliminary observations from the US, UK, Netherlands and Japan suggested that the results obtained by serological and biochemical methods show excellent agreement.

Biochemical and immunological differences between types of polioviruses appear to be greatest in the portion of the genome coding for structural proteins²⁴. However, there appears to be extensive cross-reaction between types demonstrated by both immune precipitation and immunological study of separated viral proteins (VP1, VP2 and VP3) after electrophoretic transfer to nitrocellulose sheets (western blotting)²⁵. Cross-reactivity of poliovirus proteins (VP1) with sera specific for other picornaviruses (for example, echoviruses 11 and 16) were described.

The antigenic structure of polioviruses is complex. It has been known for many years that the mature infectious virus particle expresses an antigenic determinant termed D antigen not found in empty capsids or heat-inactivated virus. Similarly, empty capsids or heat-inactivated virus express antigenic determinants (C antigen) not found on infectious virus particles.

Monoclonal antibodies can react with epitopes unique to D antigen (represented by mature infectious virus) or unique to C

antigen (represented by denatured empty capsids or heated infectious virus). Other monoclonal antibodies react with particles expressing D antigen and also with particles expressing C antigen²⁶, showing that the two antigens are indeed distinct but particles expressing them share common antigenic determinants.

Only some 50 per cent of specifically D-reactive monoclonal antibodies neutralize virus infectivity, despite binding efficiently to virus²². In contrast, monoclonal antibodies reacting with both D and C particles generally neutralize virus to high titres. C-specific monoclonals do not neutralize infectivity. Attempts were made to identify the virus structural proteins reacting with the monoclonal antibodies²⁵. It was shown that only six of twenty C-reactive monoclonal antibodies against type 3 poliovirus reacted with poliovirus proteins separated by SDS-polyacrylamide gel electrophoresis and then subjected to electrophoretic transfer. Five reacted with VP1 and one with VP3. In contrast, none of 29 antibodies of D or D + C specificity, including several which were highly active in virus neutralization, reacted in this

system. The nature of the antigenic determinants of poliovirus mediating virus neutralization and protection thus remains elusive. Recent studies²⁷ have shown that monoclonal antibodies neutralizing poliovirus type 1 react with VP1 on the native virus but not after isolation from the virus particle. Determinants seem complex, being specified by the tertiary configuration of one or more polypeptides, rather than simply by amino acid sequences. However, the findings with foot and mouth disease and with isolated polypeptides from poliovirus mentioned above suggest that under certain circumstances, relatively simple structures may stimulate neutralizing antibody.

Further progress in the international conquest of poliomyelitis may depend on the development of new approaches to vaccine design leading to more cost-effective products. While modern biotechnologies are likely to have an important role in achieving this goal, and the meeting revealed a continuing high level of scientific interest, the problems are complex and require a multidisciplinary approach. □

100 years ago

We regret to learn of the death, at Dorpat, of Dr Kreuzwald, the publisher of old Esthonian songs and poems. He was born in 1804, and studied medicine at Dorpat. When a student he began to collect songs and tales of his country-people, and in the years 1840 to 1850 he published a series of remarkable articles on Esthonian antiquities, mythology, traditions, and tales. His principal work was the publication, with annotations, of the whole of the different parts of the great Esthonian poem, "Kalewinoey," remarkable by its fine poetical feeling for nature and analysis of human feelings. It was translated into all the chief European languages. In 1877 Dr Kreuzwald was compelled to abandon his medical practice, and died in poverty at Dorpat.

THE *Official Messenger* of St Petersburg announces, on September 1, that "by order of the Emperor the admission of new pupils to the course of medical training for women, at the Nicholas Military Hospital, will be discontinued after the present term. The students will be allowed to conclude their course, after which the clinical instruction for women at the hospital will be abolished." The Medical Academy for Women, the courses of which were quite equal to those of the old Universities, had 367 students. Since 1887, when the first lady students passed the examinations, 281 ladies have completed the whole course of studies.

THE English Government having sent to Egypt three of the Woolwich balloons, we may remind our readers that balloons were taken out by the French army in 1794. But it was impossible for Buonaparte to use them, the furnace for the preparation of pure hydrogen having been lost when the French fleet was annihilated by Nelson in Aboukir Bay. Conte, the engineer of the aéronauts, was created the head of Cairo arsenal, and Coutelle, their captain, was sent on a scientific mission to Upper Egypt.

REVIEW ARTICLE

Molecular drive: a cohesive mode of species evolution

Gabriel Dover

University of Cambridge, Department of Genetics, Downing Street, Cambridge CB2 3EH, UK

It is generally accepted that mutations may become fixed in a population by natural selection and genetic drift. In the case of many families of genes and noncoding sequences, however, fixation of mutations within a population may proceed as a consequence of molecular mechanisms of turnover within the genome. These mechanisms can be both random and directional in activity. There are circumstances in which the unusual concerted pattern of fixation permits the establishment of biological novelty and species discontinuities in a manner not predicted by the classical genetics of natural selection and genetic drift.

"THE species problem is the oldest problem in biology"¹, and it is still unresolved. Despite the impressive sophistication of the mathematics of natural selection and genetic drift, there are relatively few experimental proofs of the genetic mechanisms by which species discontinuities in ontogeny and reproductive biology have arisen. There is, however, from the activities of widespread molecular mechanisms of turnover within eukaryotic genomes, a possible genetic mechanism for the origin of evolutionary novelty that is operationally different from those of natural selection and genetic drift.

Eukaryotic (and some archaeobacterial²) genomes contain substantial numbers of multiple-copy families of genes and non-coding sequences, and it has been apparent for some years that many families exhibit unexpected sequence homogeneity within and between individuals of a species. A family that is shared between several species, on the other hand, often reveals substantial heterogeneity between the species.

Family homogeneity could be achieved by several molecular mechanisms which ensure that existing members of a family might be replaced in turn with a single new variant member. The rate of replacement seems to reflect both stochastic and directional changes operating within the genomes. The modes of operation of such mechanisms have unusual genetic consequences for the manner in which variation is distributed in nature and for the concerted evolutionary progress of a group of sexual individuals. Fixation of variants in a population as a consequence of stochastic and directional processes of family turnover is defined as molecular drive³.

The dynamics of natural selection and genetic drift are modelled on the premise that mutations are unitary and passive events that rely on the activities of selection and the vagaries of drift to increase in frequency in a population⁴⁻⁶. The two processes are considered to operate within mendelian populations and lead, by definition, to adaptive and non-adaptive modes of evolutionary change⁶, respectively. The widespread fixation of variants by molecular drive is different in that it is an outcome of a variety of sequence exchanges within and between chromosomes that give rise to persistent non-mendelian patterns of inheritance. Significantly, there are circumstances in which the activities of the genomic mechanisms, in spreading sequence information between chromosomes, would lead to the progressive increase of a variant through a family more or less simultaneously in each individual of a sexual population. This concerted pattern of fixation by molecular drive may provide an explanation for the origins of species discontinuities and biological novelty.

Genomic flux

The nuclear genomes of eukaryotes are subject to a continual turnover through unequal exchange, gene conversion and DNA

transposition. These processes operate both within and between chromosomes. Some families of sequences have been described aptly as fluid⁷ because of the continually changing nature of their composition, abundance and position. Continually changing families have been described in a wide range of plant and animal species^{3, 8-15}. Some of the families consist of sequences with unknown function (non-genic families), others are either transcribed into functional RNA (ribosomal and transfer RNAs) or translated into proteins (for example, globins, histones, immunoglobulins, MHC proteins, actins)¹⁶⁻²⁶.

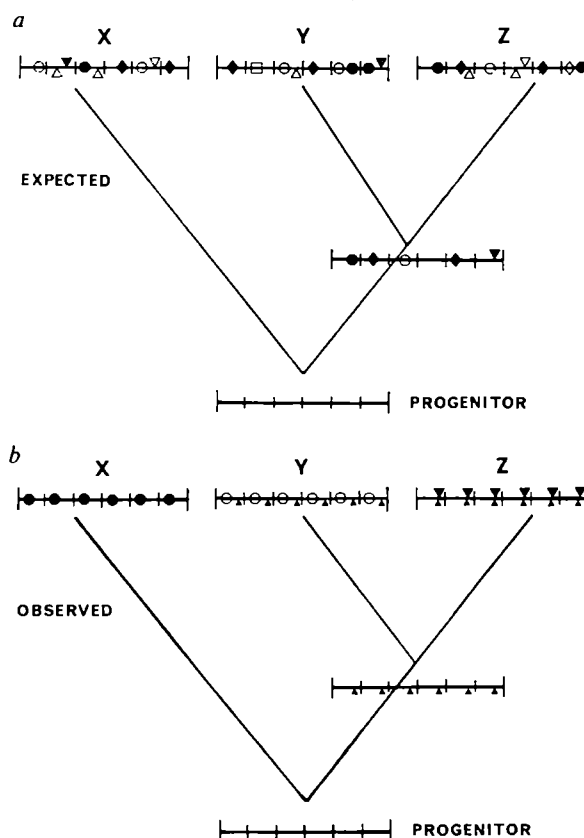

Fig 1 Schematic representation of expected (a) and observed (b) patterns of variation in a family of sequences shared by species X, Y and Z (see also refs 29, 30). If each member is free to evolve independently, then the coefficient of identity between any two randomly chosen members within a species is expected to be the same as that between two members chosen from between the species. Observed patterns reveal a high degree of within-species homogeneity. Families may be tandem (as shown) or interspersed in the genome, and may vary from two to several million members. Families may consist of copies of genes or non-coding sequences or mixtures of both.

Fig 2 A repeating unit of rDNA of *D. melanogaster*.^{16 130} 18S and 28S represent regions transcribed into functional rRNAs. INS is an insert of variable length in some repeats. ITS is an internal transcribed spacer, NTS is a non-transcribed spacer within which there are *AluI* sensitive repeats with a 240-base pair periodicity. The *AluI* motif is not present in the other six sibling species, nevertheless each species contains a diagnostic sequence variant that is present throughout the X and Y chromosome rDNA arrays (Fig 3) (see text). *n* is approximately 200 in each array. There are approximately 10 *AluI* sensitive repeats in each NTS.

The molecular mechanisms of turnover help shape the patterns of variation and affect the rate of evolution of genomic families. Although there are important differences in the evolution of individual families, similarities between members of both genic and non-genic families within a species are often greater than expected if each member were evolving independently.

Figure 1 illustrates the differences between expected and observed patterns of variation in a family that is shared between three closely related species. If each member of a family is free to accumulate mutations over time then the coefficient of identity between any two members within a species would equal that of any two members chosen at random from two different species (Fig 1a). In fact, however, many families, irrespective of their copy-number, function and genomic distribution (tandem or interspersed) display a much greater within-species than between-species homogeneity (Fig 1b).

This characteristic pattern of variation was first described in the classic studies on interspecific differences in the sequence composition of tandem arrays of genes and spacers that comprise the ribosomal DNA (rDNA) in species of frog.²⁷ The spacers reveal many mutational differences between the two species and apparently are free to diverge. Nevertheless, there are no substantial differences in sequence between the several hundred copies of the spacer-gene unit within each species. Very similar features of 'concerted' evolution have been described in other genic and non-genic families (for reviews see refs 3, 16–18, 20, 28–30). A progressive homogenization of families of sequences seems to be the fate of large proportions of species' genomes.

Molecular processes of fixation

Both stochastic and directional processes of turnover occur within nuclear genomes. The stochastic component of molecular drive results from the accidental fixation of a variant in a family and in a population through random fluctuations in the frequencies of variants within the family. Three known mechanisms can produce such fluctuations: unequal chromatid (or chromosome) exchange, gene conversion and gain and loss by transposition.

Tartof³¹ and Smith³² originally proposed that the homogenization of a family that is tandemly arrayed on a single chromosome could be a consequence of unequal chromatid exchanges.

Unequal exchange is a process which creates a sequence duplication in one chromatid (or chromosome) and a corresponding deletion in the other. There is experimental verification of mitotic and meiotic unequal exchanges in the rDNA arrays of yeast^{33 34}, and it is a possible mechanism of change in the rDNA of several species.^{16 17 31 35,36} Recurrent unequal exchange within a tandem array has the effect of expanding and contracting the copy-number of the family and the process may lead to the stochastic fixation of one or another variant member throughout the array.^{30–32}

Unequal exchange is unlikely to occur often between members of a family that are interspersed with many other sequences, particularly if they are on several nonhomologous

chromosomes. Instead it has been suggested that gene conversion is a more appropriate mechanism of homogenization within such families, and possibly also within families that are tandemly arrayed.^{37–45}

Gene conversion was first inferred from deviations from the expected 2:2 ratio of alleles in the gametes of a heterozygote individual in which the four products of an individual meiotic division remain a cluster (tetrad) so that mendelian ratios can be directly observed (tetrad analysis) (for reviews see refs 38, 46–51).

Holliday⁵² proposed that deviant ratios arise by a mismatch repair within a heteroduplex DNA region, formed during recombination between two alleles *A* and *a*, and resulting in the production of either *A+A* or *a+a*. Evidence for recombinational heteroduplexes has been obtained in *Escherichia coli*.⁵³ An equal probability of conversion in each direction results in parity in the expected frequencies of *A+A* and *a+a* overall.

Gene conversion, involving up to several kilobases of DNA, has been shown by genetic and molecular analysis to occur within a chromosome,^{38 50 54} between homologous chromosomes^{45–50} and between non-homologous chromosomes.^{37 55–57} Unlike unequal exchange, gene conversion does not alter the copy-number of a family, nevertheless random fluctuations in the frequencies of the direction of conversion (*Aa* → *aa* versus *Aa* → *AA*) may lead to the accidental fixation of one variant or another throughout a family. Gene conversion has been invoked as a mechanism that achieves (1) homogeneity between pairs of relatively closely linked genes, for example pairs of mammalian globin genes^{20 41 58}, *Drosophila* heat-shock genes⁵⁹ and silk-moth chorion genes²², (2) 'switch' in the mating type genes of yeast⁵⁴, and (3) homogeneity of amplified copies of *aprt* units in mammalian cells.⁶⁰

The directional component of molecular drive is postulated to result from persistent nonrandom exchanges of sequence information both within and between chromosomes.^{3 36,61} There are two known mechanisms that may lead to a directed homogenization of a family: one is duplicative transposition and the other is biased gene conversion.

Duplicative transposition involves the duplication and movement of a sequence from one position to another. A sequence with a high propensity to duplicate with movement of one copy to another chromosome has an increased probability of spreading in a karyotype, and hence through a population.^{62–64} Eukaryote genomes contain several such families (for reviews see refs 13, 65–67).

A bias in the direction of conversion can be observed as a departure from parity in the ratios of the expected products of conversion. The frequency of *A+A* from conversions within heterozygous cells *A+a* is consistently higher than that of *a+a*, an outcome which leads to an increasingly greater proportion of *A* in succeeding generations. The extent of bias in the conversion of different mutant sites in fungi has been observed.^{39 45–47 49} In yeast, approximately half the observed mutants depart from parity, and in some cases the departure can give rise to a 2:1 ratio in favour of the conversion of one allele by another. In other species, the deviations from parity may reveal a hundred-fold preference for the conversion of one allele by another. It has been known for several years that the conversion behaviour of a mutant is dependent on its molecular nature. Whitehouse and his colleagues^{51 68}, following from the studies of Leblond⁶⁹, have observed a predominant bias in the direction of conversion in favour of frameshift mutants containing additions of sequences, whereas single base substitutions convert with about equal frequency in each direction. Additionally, there is suggestive evidence that the 'invading' strand during heteroduplex formation is preferentially favoured during mismatch repair.⁷⁰ A mutation resulting from a frameshift addition and with a high propensity to break and invade the opposing duplex might be the basis of a high conversional bias. However, the precise molecular process creating conversion disparity during recombinational mismatch repair is unknown.

Theoretical dynamics of molecular drive

Theoretical models of fixation need to consider the process of homogenizing a family of n^* copies distributed on $2n$ (diploid) number of chromosomes in a population of N_e individuals. Although the three levels of fixation are occurring simultaneously (see later), it is convenient to consider first how a variant may become fixed within an array on a single chromosome and second the fixation of the homogenized chromosomal array in the population. A thorough treatment of the dual process of fixation using the statistical dynamics of random fluctuations in unequal exchange (or gene conversion) and genetic drift has been made by Kimura and Ohta^{64,71}, and the parameters of the process have been reviewed³⁰.

It is assumed that in a randomly mating population with an effective size N_e a multiple-copy family is evolving by means of mutation, intrachromosomal unequal exchange (or unbiased gene conversion), interchromosomal recombination and genetic drift. The simplest quantity that has been studied is the 'identity coefficient' which is defined as "the probability of two randomly chosen genes belonging to the family being identical by descent"³⁰. Consideration has also been given to the expected time required to fix a variant by molecular and genetic drift (ref 72 and T. Ohta, personal communication). The identity coefficients and fixation times can be described in terms of n^* , N_e , the rate of unequal exchange (or unbiased gene conversion), and the rate of regular recombination, together with several additional parameters concerning the mean displacement of unequal exchange and the effect of selection in stabilizing family size^{30,73} (see later).

The directional component of molecular drive, arising out of nonrandom fluctuations in the direction of conversion and duplicative transposition, has the potential to accelerate the rate of fixation^{3,36,39,49,61}. Using data on conversion frequencies and disparities between alleles of single-copy genes in fungi, Lamb and Helmi⁴⁹ have shown that, for alleles that are selectively neutral, or nearly so, fixation is largely determined by the frequency and disparity in the direction of conversion.

Fig 3 Phylogeny of seven sibling species of the *melanogaster* species subgroup of *Drosophila*, based on the tempo of evolution in four repetitive families, the rDNA, the histone gene family and two non-coding families, the '500' and '360'. For details of rDNA see Fig 2. The histone unit consists of five genes (H1, H3, H4, H2A and H2B) and four spacers (see ref 18 for details), of which there are approximately 100 copies per haploid genome of *D. melanogaster*. The '360' and '500' families are complex in organization, large in copy-number (up to 10,000) and can be distributed over several chromosomes^{12,61}. Some regions of a family unit (or complete family unit) are placed in the phylogeny at a level (A-F) determined by the extent to which the region (or complete unit) varies between taxa. For example, the rDNA coding region is the same in all species (level F), the NTS length (see Fig 2) of the rDNA shows intraspecific variation (level A), sequences within spacer regions of the NTS and the histone unit differ between all species but are homogeneous within each species (concerted evolution) (level B), the ITS length and various features of the '500' and '360' units vary between all species except between *D. simulans* and *D. mauritiana* (level C). \diamond Represents the rate of change in sequence or length, \blacklozenge represents the rate of fixation. For example, level B represents the minimal rate of fixation of the rDNA unit between the seven species due to the high rate of unequal exchange indicated by the high level of NTS length variation (level A). Although the rate of fixation of the complete rDNA unit is at level B, the rate of change in the coding regions within the unit is at F, probably as a result of selection limiting the number of mutational changes (see text and refs 3, 36, 61 for details). Me = *melanogaster*, Ma = *mauritiana*, S = *simulans*, Y = *yakuba*, T = *teissieri*, E = *erecta*, O = *orena*.

Conversion could be an important long-term factor even if the frequencies and disparities are smaller in organisms other than fungi. Unlike selection, fixation by biased gene conversion can take place without reduction in the number of offspring and, unlike genetic drift, it proceeds as easily in large as in small populations.

Nagylaki and Petes³⁹ have assessed recently the effect of biases in conversion on the sequence identity between members of a family within a single chromosome. The probability and mean time to fixation can be simulated for different values of n^* and different degrees of bias, on the assumption of one conversion event per generation between any two randomly chosen members of an array. A small conversional bias can have a dramatic effect on the probability and time for fixation. For example, the mean fixation time of a variant in an array of $n^* = 10,000$ decreases 100-fold with a conversion ratio (r) of 1/2 in favour of the variant (with parity $r = 1$, see ref 39 for definition of r). Small biases in the direction of interchromosomal conversion are expected, similarly, to accelerate the rate for achieving homogeneity within families of large copy-number interspersed with other sequences over many chromosomes^{3,36,61}.

Many factors influence the frequency and disparity of conversion, including the nature of the interacting sequences, the genomic location and the genetic and environmental background^{45,46,49,54}. A sequence fixed as a result of a high conversional bias could not necessarily retain its favoured place indefinitely given the constantly changing spectrum of extraneous influences.

As the molecular bases of transposition, conversion and unequal exchange are not understood, it is not possible to guess what influences the DNA sequences themselves might have on their efficiency (for discussion see refs 74-76). There are hints that certain sequences (or their organization⁷⁷) might act as either hotspots or coldspots with respect to the boundaries and frequencies of conversion and unequal exchange^{22,41}. Families are expected to differ in the extent to which new variants would influence the variety of genomic mechanisms of flux at any given moment in their history. It is probable that the stochastic and directional components of molecular drive are intimately related and vary from family to family.

A comparison of expected and observed times of fixation in well-defined groups of species for families of known size and composition permits some empirical assessment of the relative contributions of the two components of molecular drive to the evolutionary process.

Assessing the tempo of fixation

To assess empirically the rates of fixation, my colleagues Enrico Coen, Tom Strachan and Steve Brown have analysed variation in multigene and non-genic families within and between species of the *melanogaster* species subgroup of *Drosophila*^{35,36,61} and in interspersed and tandem families within closely related species of rodents^{43,78,79}. Interpretations of the data viewed *in toto*³ lead to the proposition that some supplementary mechanisms are probably acting to accelerate the fixation process. Additionally, the patterns of homogeneity within families that are distributed on two or more chromosomes reveal that there is a significant exchange of sequence information between chromosomes. The existence of interchromosomal exchanges influences the extent to which individuals of a population are evolving in unison.

Coen and Strachan have examined the extent of homogeneity within and between seven sibling species of the *D. melanogaster* sub-group, for families of rDNA, histone genes and non-genic families^{35,36,61}. The data are summarized in a phylogenetic scheme (Fig 3) based on the extent to which different regions of the families have become fixed for variants that can discriminate between the species (see ref 3) (Details of the families are given in the legends to Figs 2 and 3).

The families are homogeneous in each species in that they contain the same restriction enzyme sites in all members.

Different regions of the families evolve at different rates. For example, the gene regions of the rDNA (Fig 2) are invariant (level F, Fig 3). At the other extreme the non-transcribed spacer (NTS) of the rDNA and some coding and spacer regions of the histone repeating unit are sufficiently variant as to be different in all seven species (level B). Nevertheless, within each species the families are homogeneous for species-diagnostic sequence variants. For example, the *AluI* site present in each of the smaller repeating units within the NTS of *D. melanogaster* (Fig 2) is present throughout all the smaller repeats within the NTSs of both the X and Y chromosomes and in many populations of this species distributed worldwide. It is not present, however, in the NTSs of the other species. The rate of fixation in the rDNA and histone families is placed accordingly at level B (see refs 3, 36 for further explanation).

High variability in the lengths of NTSs and in the copy-number of each length within individual rDNA arrays³⁵ (level A) indicates that frequent unequal exchanges probably play a significant role in the fixation of variant NTSs.

Using the statistical dynamics of family and population size fluctuations, Ohta (ref 72 and personal communication) and my colleagues and I³⁶ have evaluated the number of generations required to fix a variant in the rDNA family where $n^* \approx 200$ per chromosome, $N_e = 10^5$, there is an upper limit in the rate of unequal exchange of 10^{-3} – 10^{-4} per generation³⁵ and an unequal displacement of 20%⁷² and 10%³⁶ of the array length. Both estimates arrive at a mean time for fixation of the order of 10^7 generations. The fixation time is close to estimates of a time of separation of 10^6 – 10^7 generations between *D. simulans* and *D. melanogaster*^{59, 80} which are based on genetic distances (Nei's measure, D , ref 81). The correlation between D and real time is extrapolated from the observed relationship between genetic distances of Hawaiian species of *Drosophila* and the age of the volcanic islands⁸². The fixation time estimates are probably an underestimation in that the rDNA is distributed on the X and Y chromosomes, both of which need to be maintained in equal frequencies during genetic drift. Additional retardation in the rate of fixation would result if the mean unequal displacement is similar to the 5% displacement observed in the rDNA of yeast³³. Although assessments of fixation times are accompanied by large variances, it is possible that both directional and stochastic processes have been involved in the fixation of rDNA variants in the relatively shorter time separating the appearance of *D. simulans* and *D. mauritiana*³ (see Fig 3). This possibility is open to experimental investigation.

Some directional process may also be required to fix variants in the '360' and '500' families having up to 10,000 members which can be distributed over several chromosomes⁶¹. These families have been fixed for diagnostic variants in all species except *D. simulans* and *D. mauritiana* (level C). If such non-genic families can tolerate large fluctuations in copy-number by unequal exchange then the time taken for fixation by stochastic processes is correspondingly reduced^{30, 73}. Wide polymorphic fluctuations in copy-number in these families (compare level A) are as yet unknown, but this possibility can be tested experimentally. The distributions of families to many chromosomes might pose additional problems with the effect of slowing down the rates of homogenization by drift^{3, 61}.

A family of $n^* = 20,000$ members that is interspersed with other sequences on up to 40 chromosomes and does not substantially alter in copy-number (the MIF-1 family)^{43, 83, 84} has revealed also the fixation of diagnostic variants between species of *Mus*⁴³. Palaeontological⁸⁵ and genetic distance⁸⁶ estimates put the time since separation of some of the species at 1 – 2×10^6 yr. Simulated estimates are available of the number of conversion generations within a single chromosome lineage that are needed to homogenize a family of $n^* = 20,000$ through stochastic fluctuations in unbiased intrachromosomal conversions, assuming one conversion per generation³⁹. For example, the mean time to fixation when $n^* = 20,000$ is approximately 4.00×10^8 conversion generations, or 10^8 yr, assuming four

Fig. 4 Schematic representation of pathways of transfer of sequence information of a variant member *a*, Intrachromosomal homogenization either by unequal exchange or biased/unbiased gene conversion *b*, *c*, Pathways of homogenization between homologous (I) or nonhomologous (II) chromosomes. Non-reciprocal sequence transfer between chromosomes could result from either duplicative transposition or biased/unbiased gene conversion. The relative rates of transfer between *a* and *b* + *c* and the rate of chromosome turnover (generation time) determine the extent to which a simultaneous change in the ratio of new to old variants occurs in each individual of a population (see text).

generations per year in the rodent species. The model is based on an individual chromosome lineage and does not consider the requirement to fix a variant on 40 chromosomes in a population of N_e individuals³⁹. Such considerations would increase the number of conversion generations required for fixation. However, given this minimum calculation, to fix a variant in a family by stochastic processes within 10^6 yr, 100 conversions per individual per generation would be required. A small and persistent conversional advantage of a variant, for example a conversional ratio (r) of 1.2 (see ref 39 for definition), would reduce the number of required conversions per individual to one per generation, in order to fix within 10^6 yr. Such estimates clearly are open to empirical investigation.

It is reasonable to postulate, for the tandem and dispersed genic and non-genic families being considered in *Drosophila* and *Mus*, that known mechanisms of directional change may have made some contribution to the distinctive patterns of species homogeneity and may have accelerated, somewhat, the process of fixation along the lines modelled by Lamb⁴⁹ and Petes³⁹ and their colleagues. Biased conversions could be taking place within tandem arrays as well as between dispersed members. Both stochastic and directional processes could be responsible for the fixation of variants in such families in these groups of species. The relative contribution of either process has yet to be assessed. It is possible that the unexpected high levels of homogeneity of many genic and non-genic families in other species is also an outcome of a combination of stochastic and directional mechanisms of turnover within nuclear genomes.

The limited independence of chromosome evolution

The analysis of sequence identity between members of families that are distributed over several chromosomes reveals that there are considerable levels of exchange of sequence information between chromosomes in many species. For example, the occurrence of the *AluI* sensitive repeats throughout the rDNA units (Fig 2) on both the X and Y chromosomes of *D. melanogaster* must be due to exchanges between these two sex chromosomes^{35, 36}. There is molecular and cytological evidence of exchanges between the chromosomes (E. Coen and G. Dover, in preparation). Because of such exchanges the evolution of the individual arrays of rDNA are not evolving entirely independently^{3, 36}.

Restrictions on the independence of chromosome evolution are also revealed by the presence of smaller subfamilies of members within large families, identified by restriction sites not present in the rest of the family^{14, 78, 79, 87–90}. Subfamilies are generally non-overlapping and are indicative of a phenomenon in which different segments of a large family are being homogenized for different variants. Surprisingly, individual subfamilies in both an abundant tandemly-arrayed family and the interspersed MIF-1 family in rodents have been found not to be localized to a single chromosome. Most subfamilies of the two families seem to be present on several chromosomes in the same proportion (refs 43, 78, and S. Brown, unpublished results). Similarly, recent studies on the chromosomal distribution of variant subfamilies in the rDNA family of humans reveal

the presence of each subfamily on all five of the chromosomes containing rDNA⁹¹

Although there are clear examples and valid arguments for the independent evolution of either subfamilies or individual members of families that have become separated on either the same or nonhomologous chromosomes^{23,92} (for example, with respect to the organizational and functionally distinct arrays of insect chorion genes^{22,93}, sea-urchin histone genes^{18,19,94}, and *Xenopus* 5S rRNA genes^{17,95,96}), there are nevertheless many karyotypically dispersed genic and nongenic families in which interchromosomal exchanges of sequences must be taking place

Sequence homogeneity between chromosomes effected by stochastic and directional processes of unequal exchange, gene conversion and duplicative transposition, has specific and unusual genetic consequences

Unusual genetic consequences of molecular drive

To understand the unusual genetic consequences of homogenizing family members between homologous and nonhomologous chromosomes, it is necessary to appreciate changes in the frequencies of a mutation in three hierarchical sets of populations

At the lowest level is the population of sequences, often dispersed on two or more chromosomes

The second level is represented by the population of chromosomes shared between a group of sexually reproducing individuals, that is, $2n \times Ne$. In a sexual population, with a haploid/diploid alternation of generations, the chromosomes can be considered as belonging to one pool, or population, of chromosomes as a consequence of random chromosome assortment during meiosis and random fusion of gametes. How far the turnover of chromosomes generates a random population of chromosomes (that is, the frequency at which a chromosome may become associated with any other in the same individual), depends on the reproductive biology and generation time of the species

The third level is the traditionally understood population of the individual diploid organisms

Molecular drive involves changes in frequency of a variant member of a family at all three population levels. It is a process which could lead to a simultaneous increase of a variant in all individuals as a consequence of the large disparity between the rates of turnover of sequences and chromosomes

The differences in rates between intrachromosome (a) and interchromosome ($b+c$) homogenization and the generation time affect the overall rate and pattern of fixation of a variant in a population of individuals (Fig 4). It is unlikely, given the experimental assessments of the intra- and interchromosomal rates of unequal exchange and gene conversion^{33,35,36,38,49,50,57,61}, that a family would become fixed for a variant within the lifetime of an individual. The coefficient of identity between any two chromosomes taken at random from within a population, with respect to the numbers of variant repeats they have acquired, would depend on the rates of intra- and interchromosomal homogenization in relation to the rates at which chromosomes within the population are being effectively randomized at each generation. The slow rate of homogenization between chromosomes relative to the fast rate of chromosomes turnover within a population (generation time) could ensure that, at any given time, there is in each individual the same average ratio of new to old variants for a particular family^{13,97}. Hence during the period of transition the differences between individuals would be kept to a minimum with respect to the changing sequence composition of their chromosomes

Accordingly, processes of sequence homogenization between chromosomes would increase the population mean of the ratio of new to old variants (and possibly the phenotype, see below), but not the variance. Different families would experience different transition times depending on the factors affecting the rates of intra- and interchromosomal mechanisms of

homogenization and the generation times of the organisms. The dynamics of change at the three interrelated levels of population (sequences, chromosomes and individuals) are complex and a mathematical description is in preparation⁹⁸

Embodied in the concept of molecular drive is the idea of "selfishness" as previously defined^{62,63} and subsequently refined^{74,75}. Molecular drive is a more inclusive notion in that it is seen as an outcome of stochastic and directional mechanisms of turnover in the genome that aid in the fixation of all manner of sequences irrespective of their copy-number, dispersion patterns or function. The mechanism suggested as the basis for the accumulation of selfish DNA is that of duplicative transposition^{62,63}, which was originally postulated to account for the increase in copy-number of transposed (mobile) elements. Studies of mobile elements in *Drosophila* and yeast show that the copy-number of mobile families are relatively small and do not fluctuate widely^{7,13}. They are small enough to be potentially eliminated by stochastic processes^{92,100}

Biological consequences of molecular drive

Several important considerations arise from genomic mechanisms of interchromosomal sequence exchange having the potential to impart genetic cohesiveness to a large panmictic population, both during and after a period of change^{3,97}

Let us consider a family of genes or non-genic sequences affecting ontogenetic growth patterns of an organism. If the rate of intrachromosomal homogenization is high then the ensuing heterozygosity between the new and old chromosomal arrays might reduce the fitness of an individual organism, leading to the loss of the array. In this circumstance the evolutionary progress of the array, as a single unit, can be monitored by classical mendelian genetics and darwinian selection. If, however, interchromosomal family homogenization is taking place, but at a rate much slower than the rate at which the chromosomes effectively constitute a random population (short generation time), then there would be a concerted change in the ontogenetic growth patterns of a group of individuals. For example, the individuals might be turning into monsters, yet there would be no significant increase in variance in the population in the degree of monstrosity. The fixation of variant sequences on different chromosomes by stochastic and directional mechanisms would induce a concerted phenotypic change in a group of individuals without the concomitant effect of disturbing relative differences in individual fitness. This is based on the assumption that small differences between individuals in the ratio of new to old variants of a multigene family during fixation have small effects on relative fitnesses. If a progressive concerted change in phenotype were ultimately to affect the viability of the organisms, then all the individuals would be affected as a group. It is possible that some aspects of the phenotypic cohesiveness of present-day species have developed along such lines (for example, see ref 101, A. Garcia-Bellido, personal communication)

The biological consequences of molecular drive may take effect, however, at a higher level. Molecular drive may contribute to a mode of accidental speciation^{3,97,102} for maximizing the genomic and phenotypic cohesiveness within a population maximizes biological discontinuities between populations. Whether a genomic dissimilarity between any two individuals from two such populations becomes a major problem of reproductive or developmental incompatibility (speciation), depends on the nature of the sequences undergoing concerted homogenization in each population. Clearly, the widespread fixation of some variants in multigene families such as histones, rDNA, globins, immunoglobins and so on, would affect the phenotype. If, in addition, future studies confirm that many non-genic families affect DNA transcription and transcript processing^{8,103,104}, or chromatin structure and chromosome behaviour^{9,12,15,97,105-112}, then the dual process of generating intrapopulation cohesion and interpopulation discontinuities would be of considerable evolutionary significance. Hitherto, all theoretical exegeses on the genetics of species discontinuities

have considered the effects of natural selection and genetic drift operating within mendelian populations^{4-6,113-122}. A progressive concerted change in phenotype of a group of individuals effected by internal processes of genomic turnover between chromosomes could not have been foreseen in the light of classical considerations of the dynamics of population change based on individual variation and "passive" allelic mutations.

The phenomenon of "hybrid dysgenesis" between populations of *D. melanogaster* in which differential accumulation of some mobile elements has occurred^{13,100,123-125} is an example of the fixation of sequences by drive (in this case by duplicative transposition between chromosomes) leading to genomic dissimilarities and subsequent incompatibilities. Additionally, it has been known for some time that hybrids between *D. simulans* and *D. melanogaster* exhibit sterility and phenotypic disharmonies as a result of numerous small genetic differences between the chromosomes of their respective karyotypes^{126,127}. "Hybrid sterility is but one expression of this cryptic divergence, which need not in itself have had a selective value"¹²⁶.

It could be that the common ontogeny of individuals of a species is due to the unfolding effects of accidentally acquired sets of variant families and is of limited adaptive significance. The clustering of species to a remarkably few of all possible modes of development (a point expressed succinctly by Lewontin¹²⁸) might reflect in part the slow rates of production and fixation of family variants having significant ontogenetic effects. A cohesive change in species phenotype by molecular drive might be rare relative to the constancy of phenotype: an interesting parallel with 'punctuated equilibria'¹²⁹. Family turnover

is continuous and is analogous to the turnover of new for old banknotes: the introduction of a new design is, however, a rare event.

Testing the theory of the origins of evolutionary novelty and species formation by means of molecular drive requires an intense study of the modes and rates of operation of the candidate genomic mechanisms. The important differential in the rates of intra- and interchromosomal sequence homogenization relative to the rate of chromosome turnover and the relative contributions of stochastic and directional components of molecular drive needs to be analysed in depth. The numbers of affected families (genic and non-genic), their chromosomal distribution and their phenotypic effects need to be assessed in genetically well-defined groups of species and populations.

Molecular drive is not an alternative to the evolutionary processes of natural selection and genetic drift in the fixation of mutational variants of single-copy genes (although single genes are not excluded from the activities of directed conversion and may also be driven⁴⁹), it constitutes a third mode of evolution that would of necessity be subject to natural selection and genetic drift in an interesting variety of real biological situations. There is no simple solution to the species problem.

I thank Richard B. Flavell, George Miklos, John Thoday, Leslie Orgel, Richard Lewontin, Francis Crick, Michael J. D. White, Claudio Schazzocchio, Alex Jeffreys, Motoo Kimura, Tomoko Ohta, Walter Bodmer and Steve Gould for stimulating conversations, and most importantly my colleagues Enrico Coen, Steve Brown and Tom Strachan for discussing their data and their ideas on genomic turnover.

A satellite altimetric geoid in the Philippine Sea

Ki-iti Horai

Lamont-Doherty Geological Observatory of Columbia University, Palisades, New York 10964, USA

A detailed geoidal map of the Philippine Sea, constructed from GEOS 3 altimeter data, revealed that the average geoidal height in the basins of the Philippine Sea decreases as the age of the basins increases. The geoidal height-age relationship is comparable with that of mid-oceanic ridges, suggesting that the cooling of the marginal sea basin's lithosphere after its formation is similar to that of the oceanic lithosphere created at the mid-oceanic ridges. The data appear to be consistent with the back-arc opening model. However, the corner flow model is also compatible with the smoothly varying geoid over the entire Philippine Sea.

THE advent of satellite altimetry has allowed a detailed delineation of sea-surface height in oceanic areas. In sea areas where oceanographic disturbances do not predominate, the height of the sea surface measured from the Earth's standard ellipsoid provides an excellent approximation of a marine geoid. As a first step in studying the mechanical and thermal characteristics of the marginal basins of the West Pacific, a geoid map of the Philippine Sea was constructed using GEOS 3 altimeter data. The Philippine Sea was chosen because it developed behind the Mariana Island Arc that is, "in many respects, the simplest and easiest of all island arc systems to study"¹.

Data adjustment

The altimeter data consist of a set of sea-surface height values measured along the satellite's track. At cross-overs between northbound (ascending) and southbound (descending) tracks, sea-surface height values are expected to coincide. In reality, however, they disagree owing to the satellite's orbit tracking error, the altimeter's instrumental bias and the noise due to variable sea-surface condition. A consistent field of sea-surface

height is obtained by making corrections for the track data's erroneous bias and tilt, so that the r.m.s. residual from all intersections in the area becomes minimal². In the area of study covering the Philippine Sea, there are 1,575 intersections among 48 ascending and 58 descending tracks. The r.m.s. cross-over residual was more than 15 m for the original uncorrected data. That was decreased to 1.5 m by removing the data's erroneous bias by a method of iterative correction³. Further tilt correction brought the r.m.s. residual to 46 cm. A geoidal map with a contour interval of 1 m was prepared based on this final corrected data (Fig. 1a).

Figure 1b is a map of the 'residual'⁴ geoid that was derived from the total geoid, as shown in Fig. 1a, by removing the spherical harmonic component of GEM-10 geoid⁵ expanded to the order of $n = 12$ and degree $m = 12$. The lower spherical harmonics of the standard geopotential model such as GEM-10 are considered to have originated from sources deeper than the Earth's asthenosphere⁶. Therefore, the residual geoid map is appropriate for the discussion of structural anomalies in the lithosphere and asthenosphere. Note that the shortest

Table 1 Average residual geoid in the marginal sea basins of the Philippine Sea

Basin	Water depth (m)	Grid for average computation		Residual* geoid		
		Grid size (deg)	No. of grids	Average and s.d. for the basin $\Delta h \pm \sigma(\Delta h)$ (m)	Reference values from undisturbed Western Pacific Δh_0 (m)	Reduced residual geoid $(\Delta h - \Delta h_0) \pm \sigma(\Delta h)$ (m)
Bonin Trough	>3,000	0.5	13	4.1 ± 1.5	0.6	3.5 ± 1.5

Okinawa Trough	>1,000	0.5	33	1.5 ± 0.8	-3.5	5.0 ± 0.8

* Lower harmonics of GEM-10 geoid, expanded up to order $n = 12$ and degree $m = 12$, removed from the total geoid.

wavelength contained in the removed component is 30° , about the same as the width of the Philippine Sea. Physiographic provinces necessary for the following discussion are summarized in Fig. 1c.

Geoidal distribution

As expected, the geoid distribution has many features in common with the gravity field which primarily reflects the bottom topography. In particular, the similarity between the distributions of the residual geoid and the free-air gravity anomaly⁷ is

remarkable. Conspicuous geoidal depressions exist on the Bonin, Mariana, Yap, Palau, Philippine and Ryukyu trenches. Geoidal bulges, corresponding to outer highs of topography and gravity seaward of the trenches⁸ are well developed along the Bonin, Mariana and Philippine trenches. All major topographic features in the Philippine Sea have geoidal signatures. The Nankai Trough is associated with a notable geoidal low. The north-south trending South Honshu (West Mariana and Iwo-jima) and Kyushu-Palau ridges are seen as disturbances to the generally smoothly varying geoid of the Philippine Sea;

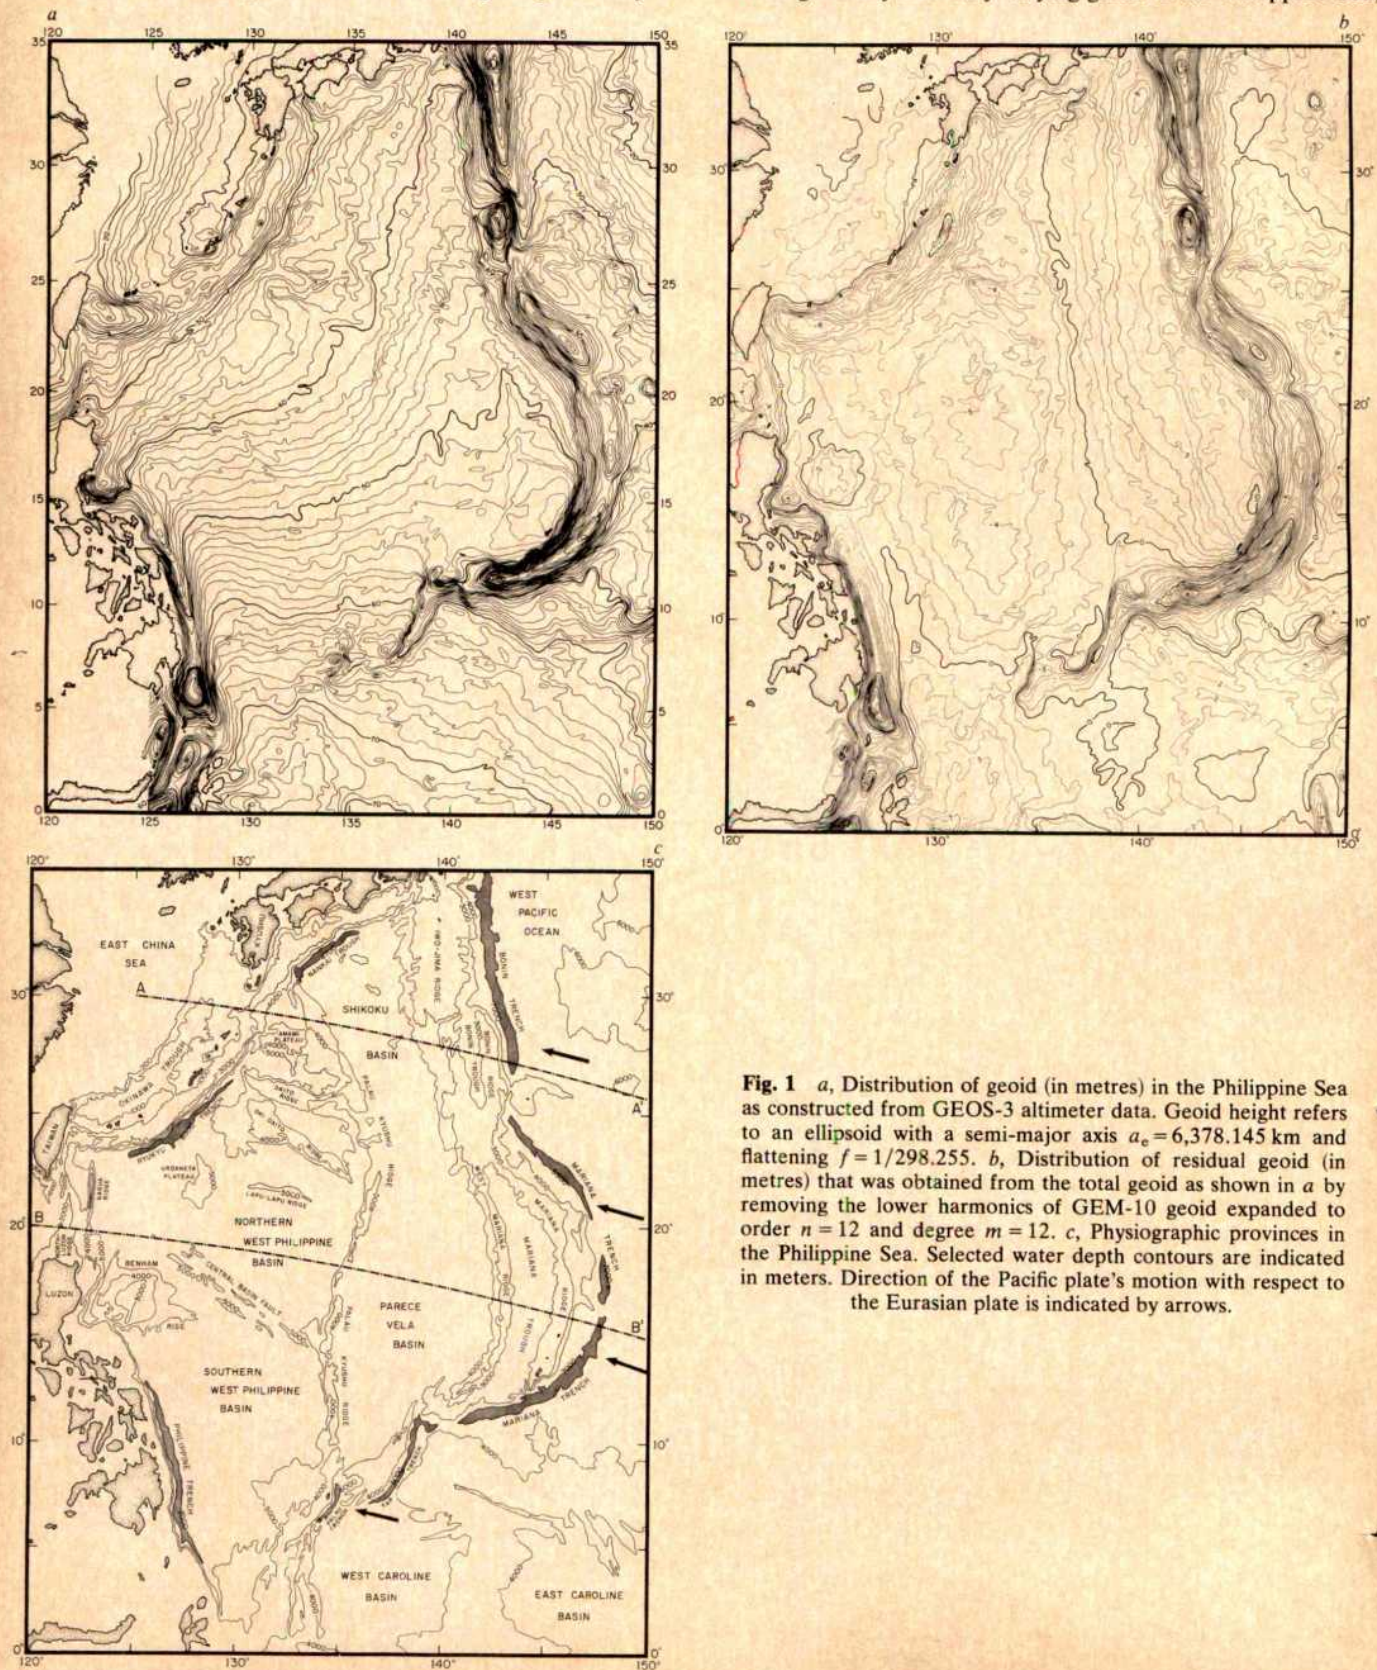

Fig. 1 *a*, Distribution of geoid (in metres) in the Philippine Sea as constructed from GEOS-3 altimeter data. Geoid height refers to an ellipsoid with a semi-major axis $a_e = 6,378.145$ km and flattening $f = 1/298.255$. *b*, Distribution of residual geoid (in metres) that was obtained from the total geoid as shown in *a* by removing the lower harmonics of GEM-10 geoid expanded to order $n = 12$ and degree $m = 12$. *c*, Physiographic provinces in the Philippine Sea. Selected water depth contours are indicated in meters. Direction of the Pacific plate's motion with respect to the Eurasian plate is indicated by arrows.

so are the Daito, Oki-Daito, Lapu-Lapu, Gagua and the Central Basin ridges that are oblique (except Gagua that is parallel) to the trend of the South-Honshu and Kyushu-Palau ridges. Over the Benham Rise and the Urdaneta Plateau, the geoidal anomalies reflect their topography, which is generally smooth, flat and shallower than the surrounding oceanic floors⁹. Quasi-circular negative geoidal anomalies are observed off Taiwan and Luzon where the Ryukyu and the Philippine trenches abutt, respectively, against the Gagua Ridge and its extension.

Geoidal height-age relationship

The distribution of the residual geoid in the Philippine Sea (Fig 1b) shows that the Philippine Sea basin's geoidal height decreases as the basin's age increases. Over the active Mariana Trough (Quaternary), the residual geoid is the highest in spite of its local topographic depression. The geoid is lower in the inactive Shikoku (early Miocene-middle Miocene) and Parece Vela (early Oligocene-middle Miocene) basins. A further decrease of the geoid from the Parece Vela Basin to the Northern West Philippine Basin (Palaeocene-Eocene) seems to reflect the difference in age as well as the mean water depth, which increases substantially from east to west across the Palau-Kyushu Ridge. It can readily be inferred that the source of the residual geoid anomaly, localized in the lithosphere and asthenosphere, is closely related to the mechanism of basin formation.

To substantiate the argument, the Philippine Sea basins' average residual geoid heights were calculated (Table 1). The basins were defined by water depth, and were divided into a set of grids of equal area. Then, at each grid point, an expected geoidal height value was computed by the weighted average method³. A GEOS 3 autocovariance was used as a weight and the range of data collection was set to 1.5 arc deg. This implies that all adjusted GEOS 3 sea-surface height values, within 167 km of a grid point, were used to estimate the expected residual geoid height at that point. The basin's average is simply an arithmetic mean of these expected values.

The average residual geoid heights of the Philippine Sea basins were then normalized against that of the Pacific Ocean floor off the Bonin and Mariana trenches. Formation of marginal sea basin is causatively closely related to the oceanic lithosphere's subduction under the arc-trench system. It is postulated that the marginal sea basin's residual geoid anomaly is meaningful only when compared with the residual geoid over the normal oceanic floor where it is free from the effect of bending due to subduction. Average residual geoid height of the Western Pacific margin was calculated with the aid of $1^\circ \times 1^\circ$ grids "in the region 400 to 500 km seaward of the trench beyond the outer rises in topography where the ocean floor is regionally undisturbed and of normal depth for its age"¹⁰. The results obtained from the latitude range from 20°N to 35°N and from 10°N to 25°N were subtracted, respectively, from the Bonin Trough-Shikoku Basin data and the Mariana Trough-Parece Vela Basin-Northern West Philippine Basin data as shown in Table 1. For the data in the Okinawa Trough, that of the Northern West Philippine Basin was used as a reference.

Figure 2 illustrates the reduced residual geoid heights of the Philippine Sea basins plotted against their ages determined from dating of the oldest sediments from DSDP Legs 6 (ref 11), 31 (ref 12), 58 (ref 13), 59 (ref 14) and 60 (ref 15) drillings and the ages estimated from the basin's magnetic lineations^{9,16,17}. The data indicate a linear relationship with a slope of 0.26 m Myr^{-1} . This is a somewhat higher slope than observed on the mid-oceanic ridges, which ranges from 0.11 to 0.19 m Myr^{-1} (W. Haxby, personal communication, see also ref 18). As McAdoo pointed out¹⁹, the geoidal anomaly over the marginal sea basins includes the effect of a dense subducting lithosphere. In the Bonin and Mariana island arc systems, the dip of Benioff-Wadati zone is among the steepest (70° – 90° in thrust angle) and its downthrust the deepest (500–700 km)²⁰ of the world's subduction systems²¹. The result is a broad and smoothly varying geoidal anomaly with its maximum located

immediately landward of the fore-arc axis. Therefore, it can be assumed that a substantial part of the anomaly due to the subducting lithosphere has already been removed as lower harmonics of GEM-10 geopotential. The anomaly's remaining component, if any, being subtracted from the observation, the slope of the geoid height-age relationship may become indistinguishable from the values exhibited by the mid-oceanic ridges.

Back-arc opening model

The Philippine Sea basin's geoid height-age relationship as summarized in Fig 2 seems to imply that the marginal sea basin's mode of cooling after its formation is similar to what the oceanic lithosphere experiences in the vicinity of the mid-oceanic ridge. The steeper slope of the linear relationship for the marginal sea basin indicates that the cooling is faster for the lithosphere of marginal sea. This is conceivable because, compared with the oceanic lithosphere created at the mid-oceanic ridge, marginal sea basin's lithosphere has a much smaller extent and in contact with adjacent lithospheres that are generally older, and hence colder, than the newly created lithosphere of the marginal basin.

The data seem to be consistent with the theory of back-arc opening^{22,23}. According to Karig²³, the basins of the Philippine Sea were created by crustal extension. After the formation of the West Philippine Basin, the Shikoku and Parece Vela basins opened and these were, in turn, followed by the opening of the Mariana Trough. An opening occurs by separating a remnant arc, formerly an active arc-trench system, from a continuously active arc-trench system that migrates seaward as spreading of the marginal sea proceeds. The opening is not a continuous

Fig 2 Average reduced residual geoid height-age relationship in marginal sea basins of the Philippine Sea. Ranges of uncertainties (error bars) of each datum point are for geoid height, standard deviation as shown in Table 1, for age, ranges of values as indicated by either direct measurement on DSDP samples or inference from magnetic lineations. Ages of the Bonin and the Okinawa troughs are uncertain. Based on the arguments of structural geology of these areas^{27,31}, the ages of Miocene (10–26 Myr) and Pliocene (0–10 Myr) were assigned, respectively, to the openings of the Bonin and the Okinawa troughs.

Fig. 3 Profiles of geoid along traverses across the Philippine Sea, *a*, a Bonin Trough-Shikoku Basin-Okinawa Trough traverse, *b*, a Mariana Trough-Parece Vela Basin-Northern West Philippine Basin traverse. Solid line, a profile of expected values calculated as a weighted average of data distributed within 167 km of the traverse. Dashed line, lower harmonics of GEM-10 geoid expanded to order $n=12$ and degree $m=12$. Adjusted GEOS-3 track data \blacksquare , ascending, \blacktriangle , descending at intersection with the traverse

process, but two successive openings are separated by a period of quiescence spanning 10–15 Myr. Thus, the Palau-Kyushu Ridge is a remnant arc associated with the openings of the Shikoku and Parece Vela basins and the West Mariana Ridge with that of the Mariana Trough.

Karig²³ modelled the crustal extension of marginal sea as caused by a thermal diapir, supposedly generated at the frictional upper surface of the subducting lithosphere. That the sinking slab's upper surface is the locus of thermal diapir generation has since been questioned²⁴. An equally important problem is whether the crustal extension due to intrusion of thermal diapir is a cause or an effect of the marginal sea's opening. In mid-oceanic ridge areas, the regional tectonic stress field is known to be tensional and the crustal accretion is believed to be due to passive upwelling of basaltic magma that is undoubtedly generated in the upper mantle. In marginal sea areas that are the zones of plate convergence, the tectonic stress is generally compressional. Recent studies tend to indicate, however, that a change of regional tectonic stress pattern from compressional to tensional²¹, or at least a release of compressional stress²⁵, is necessary for a marginal sea to open. It could be safely assumed that the mode of ascent of the thermal diapir in the marginal sea basin is similar to the passive upwelling of magma in the mid-oceanic ridges. In fact, an active spreading centre, comparable with that in the mid-oceanic ridges, has been identified and located in active marginal sea basins such as the Mariana Trough²⁶.

Among the basins of the Philippine Sea that were formed by back-arc opening, the Bonin Trough is anomalous in its mode of formation²⁷. The Bonin Trough is situated seaward of the Iwo-jima Ridge (active fore-arc) that is a complex of *en-echelon* ridge and trough systems with signs indicating nascent rifting. The Bonin Trough's frontal arc is the Bonin Ridge, an uplifted trench slope break. The Bonin Trough itself has no evidence of recent activity, but there is no doubt about its crustal extensional origin. Thus, the Bonin Trough cannot be classified as a back-arc basin, but is better termed a fore-arc basin. In spite of this fact, the Bonin Trough's geoid height-age datum appears to be consistent with the data of back-arc basins (Fig. 2). We conclude that the linear relationship between the reduced residual geoid and the age holds for the marginal sea basin of extensional origin, irrespective of whether the basin is situated fore-arc or back-arc.

Geoidal slope over marginal sea basins

Another remarkable feature of the Philippine Sea's geoidal distribution (Fig. 1*a, b*) is a uniform horizontal space gradient of the geoid over the marginal sea basins. This is best illustrated by the profiles of geoid along the traverses across the sea (Fig. 3*a, b*). Recognizing the causative relationship between the

marginal basin formation and the subduction of oceanic lithosphere, the traverses were chosen in the direction parallel to that of the Pacific plate's convergence to the Philippine Sea²⁸. The profiles show that both the total and the residual geoids' horizontal space gradients are uniform and tilt eastward on the Shikoku and Parece Vela basins. Part of the eastward tilt of the geoid is undoubtedly due to the water depth, which increases to the west in both the Shikoku and Parece Vela basins. The eastward tilt of the geoid could be explained most easily if the openings of the Shikoku and Parece Vela basins were unilateral, with their spreading centres migrated eastward with the advancing fore-arc. Then, it becomes likely that the westward decreasing geoid height is due to the age of the basin floor which increases progressively from east to west.

There is evidence, however, that both basins were formed by bilateral spreading. Based on magnetic lineation and bottom topography, Watts and Weissel¹⁶ traced a N-S trending remnant spreading centre in the middle of the Shikoku Basin. The data are highly disturbed in the eastern half of the basin, and the authors retained a possibility that the basin's mode of opening could be unilateral. A later study¹² confirmed a bilateral spreading as a more likely cause of the Shikoku Basin's opening. In the Parece Vela Basin, Mrozowski and Hayes¹⁷ located the N-S trending Parece Vela Rift and identified it as the approximate location of a remnant two-limbed spreading centre, indicating a similarity of structure and history with the Shikoku Basin.

Although a bilateral spreading in the Shikoku and Parece Vela basins is thus undeniable, the geoidal distribution of these basins shows no sign of geoidal height-age relationship within the basins. The geoid's slope is constant despite the age difference of 8–13 Myr between the centre and the margins of these basins. Analogy with the mid-oceanic spreading centre predicts a decrease of geoid of 1–2 m from the basin's centre to the margins. This is a detectable amount in the light of the nominal precision of 50 cm for the GEOS 3 altimeter measurement. There are some structural anomalies peculiar to these basins. The remnant spreading centre of the Shikoku Basin is not as morphologically prominent as the active spreading centre of the mid-oceanic ridge. In the Parece Vela Basin, the remnant spreading centre is identified as a rift rather than a ridge. In both basins, the sediment thickness increases substantially from the basin's centre towards the margins. A combined effect of these may be large enough to offset the effect of the ageing lithosphere.

In the West Philippine Basin, the NW-SE trending Central Basin Fault was believed to be a remnant two-limbed spreading centre. A recent study⁹ showed that its exact position does not precisely coincide with the Central Basin Fault. Nevertheless, the generally NNE-SSW trending spreading direction was

inferred from magnetic lineation. Figure 1b shows a symmetric distribution of residual geoid with respect to the West Philippine Basin's remnant ridge crest. In its vicinity, a decrease of the geoid for the age increment of 10 Myr is 2 and 1 m, respectively, to the NNE and SSW directions. The slope is steeper for the former, but the data for both limbs agree with that exhibited by the active mid-oceanic ridges.

Corner flow model

The eastward tilt of the total geoid over the entire Philippine Sea and that of the residual geoid over the basins east of the Palau-Kyushu Ridge (Fig 3a, b) seem to lack a correlation with the basin's lithospheric structure. They must have originated from some causes in the asthenosphere underneath or deeper. As one such cause, a corner flow looks most pertinent. Corner flow is a flow of visco-elastic material in the asthenosphere induced by the subducting oceanic lithosphere. Of the two flow systems induced along the sinking slab's upper and lower sides, that on the upper side (landward) is the more important in the present discussion. McKenzie²⁹ showed that the maximum stress heating of the viscous flow is localized in the vicinity of the island arc, directly beneath the marginal sea's lithosphere. This suggests that the thermal diapir, as a cause of marginal sea opening, is generated in the asthenosphere where the corner flow's viscous stress heating is a maximum. Thus, the corner flow model, an apparent alternative to the thermal diapir model, can actually be compatible with, as well as complementary to, it. Rheology of mantle material is, however, generally not well known. In McKenzie's calculation, the asthenosphere's viscous flow was assumed to be newtonian. It was recently shown³⁰ that the regional geoid depends strongly on the power of non-newtonian constitutive equation ($\epsilon = \eta \sigma^n$, $\eta = \text{constant}$) which gives the strain rate (ϵ) as a function of

stress (σ). McAdoo's model calculation with a sinking slab's dip of 60° showed that the exponent (n) of the constituent equation must be >3 for the slope of geoid over the marginal sea basin to tilt towards the fore-arc. Apparently, simulations for a sinking slab with much steeper thrust angles are needed to compare the numerical result with the data obtained from the Philippine Sea. The slope of the total geoid ranging from 0.8 to 1.6 m per 100 km over the Philippine Sea basin should impose an effective constraint on the rheological property of the model. It is not clear whether the corner flow is restricted within the mobile asthenosphere or, as the depth of deep-focused earthquakes indicates, penetrating into the Earth's deep interior. If the corner flow's convective cell is shallow, the slope of the residual geoid will be more appropriate for the theory.

Conclusion

In addition to the bottom topography, marine geology, magnetic anomaly and heat flow, the geoid derived from satellite altimeter data has proved useful in studying the marginal sea's history. The idea of comparing the geoid of marginal sea basins with that of the oceanic floor, where the lithosphere is in a pre-subduction state and is undisturbed from the bending effect, is probably the most important. Data of bottom topography and heat flow processed in a similar fashion will serve to develop a systematic theory of marginal sea formation. This study will be extended to other marginal seas in the Western Pacific Ocean.

The original draft of this article has been revised substantially by constructive criticisms given by Dr D. E. Karig of Cornell University. This work was supported by the Office of Naval Research under contract N00014-80-C0098-B. Lamont-Doherty Geological Observatory Contribution No. 3666.

Over the past decade oceanographers have become increasingly aware of an intense and compact ocean 'mesoscale' eddy structure (the ocean weather) that is superimposed on a generally sluggish large-scale circulation (the ocean climate).

Traditional ship-based observing systems are not adequate for monitoring the ocean at mesoscale resolution. A 1981 experiment mapped the waters within a 300×300 km square south-west of Bermuda, using a peripheral array of moored midwater acoustic sources and receivers. The variable acoustic travel times between all source-receiver pairs were used to construct the three-dimensional (time-variable) eddy fields, using inverse theory. Preliminary results from inversions are consistent with the shipborne and airborne surveys.

Fig 1 Geometry of the 1981 Ocean Tomography Experiment S1 to S4 designate the acoustic source moorings, R1 to R5 the acoustic receiver moorings, and E1 and E2 the environmental moorings with current meters and temperature-pressure (T-P) recorders E3 is a current meter mooring set by F Schott Acoustic moorings also carried T-P recorders The receivers R1 and R5 consisted of short vertical arrays Floats at 1,000 m depth with 1,000 lb buoyancy provided taut moorings, thus eliminating wave forces and reducing horizontal excursions The position of each acoustic source and receiver was monitored by a 10-kHz source (placed just beneath the low-frequency tomographic sources and receivers) which interrogated three bottom transponders T dropped a few kilometres from the mooring (shown for S4) The plan view shows the grid for CTD/XBT surveys in March, May and July In addition, AXBT drops at the CTD positions were carried out in April and June The experimental area is over the Hatteras abyssal plain with depths varying between 5,300 and 5,600 m

THE chief obstacle to understanding the ocean circulation is the overwhelming difficulty in observing it The ocean is an enormous turbulent fluid fluctuating on all space and time scales Largely as a result of the MODE expedition¹ in 1973, it has become clear that a 'mesoscale' variability, closely analogous to weather systems in the atmosphere, is superimposed on the large-scale ('climatic') flow field But the mesoscales are disparate a few months and several hundred kilometres in the oceans as compared with a few days and several thousand kilometres in the atmosphere

There has been no perceived national or international requirement to lead towards a large-scale ocean observation network The cost in ship time is prohibitive (10 full-time vessels for 1 Mm² (1,000 × 1,000 km, about one-third the Mediterranean) Interior *in situ* sensors cannot transmit data by conventional means because the ocean is opaque to electromagnetic radiation For the same reason remote sensors in space cannot penetrate the ocean interior

But the ocean is transparent to sound Acoustic tracking of submarines goes back to World War I and tracking of neutrally buoyant floats from ships or shore stations is now a widely used oceanographic tool However, there has been no previous

attempt to exploit the properties of the sound field itself as a way of attacking the fundamental observation problem

The present experiment derives from a proposed scheme² for measuring the field of sound-speed fluctuations within a volume by acoustic transmission through the volume along many diverse paths It was called 'ocean acoustic tomography', in analogy with the medical X-ray procedure CAT (for computer-assisted tomography) The procedure is best illustrated by reference to the 1981 experiment (Fig 1) We chose a 300-km square in the same general area occupied by the MODE experiment¹ with a known mesoscale variability (MODE involved six ships and 25 conventional moorings) The 300-km dimension permitted adequate mapping from a ship in three weeks' time for comparison with the acoustic method, and the use of existing acoustic hardware Sound pulses emitted at each of the four sources S were recorded at each of the five receivers R Sound-speed in the ocean is predominantly a function of temperature, a cold eddy within the observation square will delay the arrival of any transmission through the eddy

There is a minimum in sound-speed (Fig 2) around 1 km depth forming a 'sound channel' which traps some of the acoustic energy This waveguide, which is the dominant feature of mid-latitude acoustic propagation, is useful here in two ways (1) acoustic rays that are refracted back towards the axis before intersecting the surface and bottom lose little energy through the boundaries and thus can be detected over several thousand kilometres (megametres), and (2) steep rays which sample the entire water column and generally arrive early can be distinguished from flat late rays which remain nearer the axis, and in this way something can be learned about the depth dependence of the ocean disturbances A very shallow disturbance affects only the very steep rays with shallow upper turning points, a deep disturbance alters the travel times of both steep and shallow rays

For each of the 20 source-receiver pairs (Fig 2 represents one of these) we record roughly 10 multipaths, giving a total of about 200 travel times for each transmission The number of data points grows geometrically with the product $R \times S$, as compared with the sum $R + S$ for conventional spot measurements and the path integration reduces the noise from local finestructure

One needs a procedure for converting this information into maps or spectra (or other interesting representations) of the ocean temperature field Generally the system is underdetermined, and there is an infinity of solutions 'Inverse theory' can be used to constrain the solution by solving for the smoothest field, or finding the unique solution consistent with *a priori* knowledge of the field covariance (The procedures of medical tomography are a specialized subset of the available mathematical tools)

The procedure depends critically on the resolution, identification and stability of multipaths over large ranges The scheme² proposed in 1979 depended on theoretical estimates, but there was no direct experimental evidence that any one of the three requirements could be met Positive results, rather

Fig 2 Ray (multipath) diagram from source S1 to receiver R3 for upward (+) launch angles only The identifier gives total (upper plus lower) number of ray turning points The associated measured and predicted arrival structures are plotted in Fig 3 The range-averaged sound-speed profile from S1 to R3 is shown to the left

Fig 3 Comparison of measured arrival pattern with the WKBJ predicted impulse response on year day 64 for S1 to R3 transmissions. The daily mean pattern is formed from 24 hourly transmissions. Travel times for the peak arrivals are shown for each hour. Only peaks with signal-to-noise ratios exceeding 15 dB are plotted. Selected arrivals are identified, for example, +14 (715 m) refers to an upward launch angle with 14 ray turning points, the upper turning point being at 715 m depth. Some of the associated rays are identified in Fig 2. The non-geometric arrival refers to a ray with a turning point just above the receiver. Surface reflected a non-geometric arrivals are not included in Fig 2.

better than expected, were subsequently obtained during 48 days of transmissions at 10-min intervals over a 900 km path eastwards from a source moored near Bermuda³. A northward 300-km transmission that was intersected by a southern meander of the Gulf Stream gave similar results⁴. These experiments also provided experience for solving two crucial engineering problems: mooring position keeping and time keeping.

Measurements

The acoustic sources are patterned after the neutrally buoyant SOFAR floats that have been used extensively to track subsurface circulation in the Atlantic^{5,6}. Each source consists of four parallel 1-ft diameter aluminium tubes that are tuned for resonance at 224 Hz and have a bandwidth of 20 Hz. They are driven at the closed end by a flat circular plate of piezoelectric material. A microprocessor controls all source timing (on-off scheduling), including the phase modulation of its 224-Hz carrier. Briefly, the modulation is a 127-digit maximal length shift register sequence⁷. The autocorrelation function of the sequence is sharply peaked and has no sidelobes. Each digit comprises 14 cycles of the carrier and therefore has a duration of 62.5 ms. This is the width of the correlation peak and establishes the multipath resolution of the system. A sequence of 127 digits lasts nearly 8 s, which more than covers the time spread between the first and last arrivals (Fig 3). A transmission consisting of 24 consecutive sequences lasts nearly 192 s, which is roughly the decorrelation time of the ocean due to internal waves for this experiment. Coherent averaging of the 24-sequence receptions affords signal-to-noise gain. One can think of each transmission as being equivalent to the transmission of 62.5 ms pulses at 8 s intervals repeated 24 times. Coherent summation produces a single intense pulse^{8,9}. The transmitted power level is quite low, about 14 W ($186 \text{ dB } \mu\text{Pa}^{-1}$ at 1 m), for a total of 2,700 J per transmission (about the same energy as in the prolonged grunt of a blue whale heard off the coast of Chile¹⁰) but when this energy is 'compressed' into 62.5 ms pulses it can be recorded at typically 25 dB signal-to-noise ratios, leading to a theoretical travel time precision of 2 ms for a resolved arrival.

The acoustic receivers are microprocessor controlled devices. The arrival time structure of the multipath field between source and receiver is obtained by cross-correlating the coherently averaged incoming signal with a stored replica of the transmitted signal. Some receivers performed the cross-correlation *in situ* and stored only the time of arrival of multipath peaks, while others simply stored signal samples for later on-shore processing. Reception times were synchronized to source transmission times. Transmissions were at hourly intervals (for tidal correc-

tion and to suppress internal wave noise) on every third day only (to conserve batteries).

To provide a time base accurate to better than 10 ms, each source and receiver was equipped with a rubidium atomic frequency standard to make daily measurements of the frequency offset of a considerably less stable (but of lower power) continuously running quartz crystal clock. The frequency offsets are integrated to yield time corrections. It is necessary also to correct the travel times for mooring excursions. These were measured with bottom transponders to a precision of $\sim 1.5 \text{ m}$ (1 ms for a line-of-sight displacement).

Travel times

The procedure depends critically on the resolution, identification and stability of multipaths over large ranges³. The predicted arrival pattern (Fig 3) is derived from a generalization to ray theory¹¹, and it matches the measured pattern rather well. This identification, based on travel time, was checked for ray inclination at receivers R1 and R5 which were equipped with vertical arrays¹², and in no instance did the difference between measured and predicted inclination exceed the experimental error.

Figure 4 shows this arrival pattern on a reduced scale over a 100-day period. Multipath peaks are plotted as single points, and only those paths whose signal-to-noise ratio exceeded 15 dB are shown. The relative pattern is stable, some weak late arrivals are surface and bottom reflected and have not been used in the analysis. The 2 s drift of the raw pattern towards

Fig 4 Multipath arrival structure S1 to R3, before and after corrections for clock drifts and mooring displacements. Transmissions were over 24 h on each third day, starting 18 February (year day 49). The unstructured patterns on days 43 and 46 (before transmission) show processed noise. Gaps in the source displacement are due to missing data.

earlier arrival is almost entirely associated with the gain of the receiver clock (as measured by the rubidium standard). Horizontal excursions of the moorings provide a lesser correction. The high frequency excursions can be related to tidal motion. The arrival pattern corrected for clock drift and mooring motion provides the database for the tomographic inversion.

Comparison of tomographic with traditional measurements

There is a basic problem of comparing two fields that are not the same. The CTD (conductivity/temperature/depth) surveys took almost three weeks (during which time the fields changed), the acoustic surveys provided almost synchronous snapshots (one can think of them as surveys conducted at 3,000 knots).

Panels *b*, *e*, *f*, *i* of Fig 5 show the sound-speed maps from the first two CTD/XBT cruises¹³. Nominal station spacing was 50 km but near the centre the spacing was halved (Fig 1). During the second cruise 10 additional 1,500-m CTD casts extended the grid 100 km westward. Panel *a* was inferred (using representative *T-S* relations) from AXBT drops on 13–14 April at positions of the CTD stations. (The AXBT's were from P-3 aircraft supported by NAVOCEANO Standard AN/SSQ36 probes (to 300 m depth) were used, with temperature calibrations (to $\pm 0.15^\circ\text{C}$) as described in ref 14.) Sound-speed was computed¹⁵ and then contoured using an objective interpolation scheme like that used in MODE¹⁶. The necessary weights were computed using a gaussian correlation function of 100-km scale.

The March map (days 66–85) shows a cold eddy nearly in the centre, evidently embedded in a background gradient with warmer water to the north. The May map (days 120–139) shows the same cold eddy displaced about 200 km to the west, weakened, and perhaps split in two. A new cold eddy, smaller than the original, has appeared in the south-eastern corner.

The four central charts are from the tomographic inversion. The sound-speed field is modelled by specifying a covariance function for the perturbations around a basic state. The horizontal covariance function is homogeneous, isotropic and gaussian with a decay scale of 100 km. The vertical structure is made up of empirical orthogonal functions calculated from the MODE dataset¹.

The tomographic maps show a slow westward movement and slight weakening of the central cold eddy, and the appearance of a new cold centre in the south-east corner, consistent with the CTD surveys. A premature failure of receiver R4, followed by R2 and R3, has so far prevented the plotting of the tomographic chart for the time of CTD II, as had been intended. (The failures were the result of a faulty battery batch, the remaining receivers and all sources functioned normally and will eventually permit limited inversions through the full experimental period.) The chart sequence as shown implies a remarkably stable pattern for the first 40 days, followed by rapid changes in the subsequent 20 days. This interpretation of a 'jumpy' eddy movement is consistent with the observed stability in travel time to R1 until day 110, with rapid changes thereafter in the sense indicated by the charts in Fig 5. Similarly, 'stick charts' of the measured currents at the environmental moorings E1 and E2 are uneventful until day 110 and then change rapidly¹³. The indicated sequence is as follows¹³.

- Days 62–91 A large cold eddy remains nearly stationary at a position north-east of E1 where it was observed during CTD I. Under its influence the E1 currents flow generally to the south-east and the E2 currents flow to the east.
- Days 91–110 The cold eddy moves slowly WSW to a position west of E1, near where it was seen during the AXBT flight on day 103. (This corresponds to the times of the tomographic inversions.) As a result the flow of the shallow E1 current meter (137 m) turns counterclockwise to the north, and the

Fig 5 Mosaic of sound-speed anomaly charts in the 300×300 km square (centred at 26°N , 70°W). *b*, *f* are from the first CTD survey (CTD II includes an additional 100 km strip to the west), *a* is from the AXBT survey. The four central charts are from the tomographic inversions, assuming travel time error bars of 10 ms. Year days 1981 are indicated below, the tomographic inversions are referenced to the travel time on day 73. *f*–*i* at 700 m depth gives sound-speed departures δC relative to $1,505.9 \text{ m s}^{-1}$, *a*–*e* at 350 m depth relative to $1,521.7 \text{ m s}^{-1}$, with contour interval 1 m s^{-1} , departures above $+2 \text{ m s}^{-1}$ and below -2 m s^{-1} are shaded. Points give positions of CTD and AXBT casts, and of acoustic and environmental moorings (see Fig 1 for mooring identification).

Fig. 6 Relative travel times at hourly intervals for every third day (transmission day) from two sources to north station are portrayed by the sloping line segments, short or missing lines are the result of low signal-to-noise levels. The right-hand scale shows the corresponding barotropic displacement of the Gulf Stream. *, Positions of the North wall of the Gulf Stream inferred from sea-surface temperature measured by NOAA-6 satellite.

flow of the deep (835 m) current meter turns completely around to the west (The different degrees of turning of the shallow and deep current meters are caused by the north-east tilt of the eddy axis). The flow of E2 turns slightly clockwise to the ESE.

- Days 110–130 The first cold eddy rapidly moves west to the edge of the experimental box and a second cold eddy appears in the south-east quadrant, where they are seen during CTD II. The flow is generally to the north-west at E1 and south-west at E2.

The above interpretation is supported by the good agreement between the measured currents and those from the dynamic height maps during CTD I and CTD II. We conclude that the tomographic inversions are consistent with the CTD and current meter observations.

The tomographic charts in Fig. 5 are the result of preliminary inversion for a few transmission days, using only a few paths per source–receiver pair. Work is in progress to optimize the procedure and to attempt inversions subsequent to day 103 with the degraded array (unfortunately the number of data points not only grows but also declines geometrically with the number of moorings).

There are two basic problems with the inversion process: initialization and linearization. Work on these problems has started. In this preliminary report we follow the simplest initialization procedure: for each source–receiver pair we use only the difference in travel time reckoned from the (known) ocean state on day 73 to compute perturbation fields relative to day 73, and map the combined (initial plus perturbation) fields. For very long time series one would refer the perturbation maps to a climatological mean state which (probably) suffices for ray identification purposes (Doubtful cases could be tied down with AXBT flights). Any errors in the assumed mean state will, of course, be retained in the combined maps.

An equivalent (and better) procedure is to use absolute travel time for the known initial (or mean) ocean state to correct the array configuration for a navigational error of ± 0.5 km, and to use absolute travel times in the subsequent inversions. (This involves only 15 independent constants, for example, the x , y positions of eight moorings relative to some arbitrary reference mooring, plus an arbitrary coordinate rotation. The present procedure involves 20 independent constants, for example, the absolute travel times on day 73 for each source–receiver pair.)

Formally, the tomographic procedure is independent of CTD surveys, these are used only to remove navigational errors. It

is expected that the GPS satellite system and sea floor localization procedures¹⁷ will determine the configuration of future arrays to within ± 1 m. At this point a knowledge of the climatological state is required only for ray identification, and the perturbation maps are free from initialization error.

In our linearized inversion procedure we ascribe perturbations in travel time to perturbations in sound-speed along the unperturbed ray paths. But rays emerging from mesoscale eddies have turning depths that may differ sufficiently from the unperturbed turning depths so that a significant part of the travel time perturbation is accumulated outside the eddy¹⁸. Generally the errors are too large to be neglected, yet sufficiently small to suggest an iteration procedure¹⁹. This has not yet been attempted.

Remote stations

The sources were monitored at remote facilities to assure their proper functioning, and to gain experience with long-range transmissions. In this connection we observed a systematic fluctuation in travel time over a northward 2,000-km path across the Gulf Stream (Fig. 6). (On calendar days 52, 55, 58 the receptions from source S2 were poor, on day 61 this source was recovered, found faulty, and another source deployed. No other source anomalies were seen during the remaining six months.) At the midpoint of the 50 days record, the travel time was shortened by 0.8 s. This is the result of a 200-km northward displacement of the Gulf Stream, with the associated decrease in the amount of cold slope water over the path²⁰. (Satellite sea surface temperatures support this interpretation.)

Discussion

The preliminary report of the 1981 experiment indicates that ocean mapping with mesoscale resolution can be performed tomographically over substantial areas. There is, of course, a shortcoming in measuring only the sound-speed field. But in regions of tight T - S relations, or where the disturbances are associated mostly with vertical displacements of the isopycnals, the sound-speed perturbation can be mapped into density perturbations with accuracies adequate for computing geostrophic currents²¹.

Two developments are planned for the future. In the autumn of 1982 we plan to make reciprocal transmissions²² at 300 km ranges and use the difference in the oppositely directed travel times to infer the water velocity along the ray paths (velocity tomography). Subsequently we plan to establish an array of megametre dimensions to measure the variability of an ocean gyre²³. Here the tomographic principle would be used to obtain vertical resolution, in the horizontal directions advantage is taken of the integrating properties of long range sound transmissions, opening the way to true ocean-basin scale measurement programmes.

We thank C. Spofford for discussion and advice. J. Dahlen furnished the T - P recorders. Many people have helped, but we are particularly indebted to Paul Boutin, S. Liberatore, F. Schuler, A. Bradley, J. Kemp and M. Jones of Woods Hole, to F. Dormer, K. Hardy, B. Ma, D. Peckham and R. Truesdale at Scripps, and to B. Grant and S. Johnson at MIT. The work has been supported by the Office of Naval Research and by the NSF. The Atlantic Oceanographic and Meteorological Laboratory of NOAA provided support for three CTD/XBT cruises of the ship *Researcher* and for J. S. The US Navy Oceanographic Office supported the two AXBT flights.

Brain spectrin, a membrane-associated protein related in structure and function to erythrocyte spectrin

Vann Bennett, Jonathan Davis & Walter E. Fowler

Department of Cell Biology and Anatomy, The Johns Hopkins University School of Medicine, 725 North Wolfe Street, Baltimore, Maryland 21205, USA

An immunoreactive analogue of erythrocyte spectrin has been purified from brain membranes. This protein co-sediments with and cross-links actin filaments, associates with spectrin-binding sites on erythrocyte membranes, and has been visualized by rotary shadowing as an extended, flexible rod. The brain spectrin comprises 3% of the total membrane protein, and may have a major role in mediating linkage of actin to membranes.

MEMBRANE-associated forms of actin have been observed in many types of cells and are thought to participate in cell motility, adherence of cells to surfaces, determination of cell shape and in the organization of cell-surface integral proteins (for review see ref 1). A direct linkage has been demonstrated between actin and integral membrane proteins in lymphocytes^{2,3}, but the polypeptides required for these associations are unknown. Actin is a component of erythrocyte membranes^{4,5} and its mechanism of association with this simple membrane has been established in detail (reviewed in refs 6, 7). Erythrocyte actin is bound to spectrin in a complex perhaps involving band 4.1 (refs 8–10). Spectrin is an extended rod-like molecule present as a tetramer formed by head-to-head association of dimers¹¹, spectrin dimers consist of two different subunits, arranged as parallel chains. The β -subunit of spectrin is bound to ankyrin^{12–16}, which in turn is associated directly with the cytoplasmic domain of band 3, the major membrane-spanning protein in erythrocytes^{17–19}.

It has been assumed that the association of actin with erythrocyte membranes is not relevant to the arrangement of actin in other cell types, where spectrin could not be detected by radioimmunoassay²⁰. However, polypeptides immunologically related to erythrocyte spectrin^{21,22} and ankyrin^{23,24} have been detected in brain and other tissues. These cross-reacting proteins include soluble and membrane-associated forms. A class of soluble analogues of ankyrin and spectrin have been identified as high-molecular weight microtubule-associated proteins (MAPs)^{22,24}. MAP1, a group of polypeptides of molecular weight (M_r) ~370,000 (370K), contains a component which is related to ankyrin, while MAP2, a polypeptide of M_r 300,000, shares antigenic sites with the α -subunit of spectrin. MAP2 shares with spectrin the ability to bind to actin²⁵ and the shape of an extended rod²⁶, but lacks membrane-binding activity. Here we describe another immunoreactive analogue of spectrin from brain which binds to actin, associates with spectrin-binding sites in erythrocyte membranes, and is an extended rod-like molecule. This spectrin analogue comprises 3% of the total membrane protein, and is a suitable candidate for having a major role in mediating linkage of actin to membranes.

Purification of spectrin analogue from brain membranes

Brain membranes contain a prominent pair of polypeptides of M_r ~260K and 265K which cross-react with affinity-purified antibody against erythrocyte spectrin (Fig 1). Membrane fractions from kidney, liver and testes also contain polypeptides of similar molecular weight which cross-react with anti-spectrin antibody, but brain membranes were the richest source of these polypeptides (not shown). In liver, cross-reacting polypeptides of M_r 260K and 265K were localized exclusively in the plasma

membrane fraction (Fig 2). The mitochondria, nuclei and soluble fractions all contain polypeptides unique for each fraction which cross-react with anti-spectrin antibody, but none are of molecular weight 260K or 265K. The significance of multiple cross-reacting polypeptides is unknown, and further studies with each polypeptide are required. The reactions are specific in that there was no cross-reaction of these polypeptides with non-immune antibody (Figs 1, 2) or with antibody against ankyrin or band 3 (not shown). A possible explanation is that functional domains of spectrin are conserved as discrete amino acid sequences in other polypeptides and have been combined with other activities to form proteins distinct from spectrin. Here we present a detailed study of the 260K and 265K cross-reacting polypeptides.

Fractionation of brain membranes by differential centrifugation or sedimentation on gradients of sucrose or sucrose-Ficoll did not yield membranes significantly enriched in these polypeptides, and only myelin lacked the polypeptides (not shown). Therefore, total membranes depleted of myelin were used as starting material for purification procedures. These membranes contained ~75% of the 260K/265K polypeptide present in total brain homogenates. The 260K/265K polypeptides can be solubilized from brain membranes by extraction with 1 M KCl or at low ionic strength with 0.2 mM Na-EGTA (not shown). Extraction with low salt was more selective, and was therefore used to solubilize the protein for purification. The immunoreactive 260K/265K polypeptides were purified to homogeneity by precipitation with ammonium sulphate, gel filtration and finally rate zonal sedimentation on sucrose gradients (Fig 1).

To examine the cross-reaction between spectrin and the brain protein, ¹²⁵I-labelled brain protein was immunoprecipitated by antibody against spectrin, and this binding was displaced completely by unlabelled spectrin (Fig 1B). The brain protein displaced binding of ¹²⁵I-labelled spectrin to antibody by a maximum of 20% (Fig 1C). The limited displacement achieved by the brain protein occurred in the same range of concentration as displacement by erythrocyte spectrin. Thus, only 20% of the antigenic sites recognized by our antibody in erythrocyte spectrin are shared by the brain protein, but those sites which are common between these proteins are well conserved. The fact that the brain and erythrocyte proteins are only partially cross-reactive could explain previous negative results of radioimmunoassay for spectrin²⁰.

The possibility that our antibody was reacting with a minor contaminant which co-migrated with the brain polypeptides was excluded by comparing peptide maps of each brain polypeptide with maps of polypeptides immunoprecipitated by the antibody (Fig 3). The total brain polypeptides and the fraction immunoprecipitated with anti-spectrin antibody produced almost identical peptide maps. Thus, the antibody recognizes a major constituent of each polypeptide.

Fig. 1 Purification from brain membranes of a protein which shares antigenic determinants with erythrocyte spectrin. Fractions at various stages of purification were analysed by SDS-polyacrylamide gel electrophoresis on 3.5–17% exponential gradient gels^{22,24} (A). Polypeptides were visualized by staining with Coomassie blue (CB); those cross-reacting with erythrocyte spectrin were identified by electrophoretic transfer from polyacrylamide gels to nitrocellulose paper, followed by overlay of the nitrocellulose with $1 \mu\text{g ml}^{-1}$ affinity-purified rabbit antibody against human erythrocyte spectrin or with non-immune antibody followed by ^{125}I -labelled Protein A^{22,24}. Immunoreactive bands were then detected by autoradiography. Samples are: a, pig erythrocyte ghosts; b, pig brain membranes; c, low ionic strength extract of brain membranes; d, soluble protein recovered from ammonium sulphate precipitation of sample c; e, pooled fractions from gel filtration; f, pure protein from sucrose gradients. Immunoprecipitation of ^{125}I -labelled pure protein (lane f) and ^{125}I -labelled pig erythrocyte spectrin by anti-spectrin antibody were measured as described elsewhere^{22,23}. Binding of ^{125}I -labelled brain protein by anti-spectrin antibody (100 nM IgG) was displaced by unlabelled erythrocyte spectrin (B). C, binding of ^{125}I -labelled erythrocyte spectrin by anti-spectrin antibody (7 nM IgG) was displaced by unlabelled erythrocyte spectrin (○) and partially displaced by unlabelled pure brain protein (●). Frozen grey matter from pig brain (125 g) was homogenized in 800 ml of 0.32 M sucrose, 2 mM Na-EGTA, 200 $\mu\text{g ml}^{-1}$ phenylmethylsulphonyl fluoride (PMSF) (v/v) diisopropylfluorophosphate, 3 $\mu\text{g ml}^{-1}$ pepstatin A, pH 7.0. The 900g supernatant of this suspension was pelleted at 30,000g for 25 min to collect the crude membrane fraction. This fraction was depleted of myelin by centrifugation for 40 min at 30,000g through 0.8 M sucrose. The myelin-depleted membranes were washed successively by centrifugation for 25 min at 30,000g with homogenization buffer, followed by 10 mM sodium phosphate, 2 mM Na-EGTA, 50 $\mu\text{g ml}^{-1}$ PMSF pH 7, and finally 2 mM Na-EGTA, 50 $\mu\text{g ml}^{-1}$ PMSF pH 7. The washed membranes (1.6 g protein) were extracted at 37°C for 60 min in 800 ml of 0.2 M Na-EGTA, 0.5 mM dithiothreitol (DTT), 50 $\mu\text{g ml}^{-1}$ PMSF pH 7. The suspension was pelleted at 200,000g for 30 min and the supernatant (120 mg extracted protein) was adjusted to 45% saturation with solid ammonium sulphate. The precipitated proteins were dialysed overnight against 1 M urea, 20 mM glycine, 2 mM Na-EGTA, 1 mM NaN_3 , 0.2 mM DTT, and centrifuged at 200,000g for 3 h. The supernatant was applied to a Sephacryl S400 gel filtration column (2.6 × 90 cm) equilibrated with urea buffer. Fractions containing the 260K polypeptides eluted near the void volume. The protein was precipitated with ammonium sulphate, dialysed extensively against 0.2 M Na-EGTA, 0.5 mM NaN_3 , 0.2 mM DTT pH 7, then centrifuged at 200,000g for 90 min. The supernatant was fractionated on 10–30% linear sucrose gradients in dialysis buffer using a Beckman V Ti 50 rotor (14 h at 36,000 r.p.m.). The gradient fractions with the purest protein (at about a sedimentation rate of 11S) contained 1.2 mg of protein. An additional 2 mg of less pure protein was recovered from adjacent fractions.

A feature which distinguishes spectrin from other high-molecular weight actin-binding proteins, such as filamin and MAP2, is the presence of two distinct polypeptide chains. In this respect, the brain protein resembles spectrin as the 265K and 260K polypeptides are clearly different by peptide mapping (Fig. 3). The two chains co-purify in a 1:1 molar ratio, and both polypeptides co-sediment with actin (see below). The brain protein has a molecular weight of 1,090,000, calculated from preliminary hydrodynamic values ($R_s = 240 \text{ \AA}$, $s_{20,w} = 10.8$, \bar{v} assumed to be 0.73). This protein is therefore a tetramer with two copies of each subunit.

The peptide maps of α - and β -chains of erythrocyte spectrin are dissimilar from either chain of the brain protein (Fig. 3). It is of interest that peptide maps of human and pig erythrocyte spectrin differ by at least 60% and that antibody against human spectrin binds with a lower affinity to pig erythrocyte spectrin (not shown). Erythrocyte spectrin evidently does not have a highly conserved amino acid sequence. The fact that the peptide fingerprints of the brain protein differ from those of erythrocyte spectrin does not rule out functional homology between these proteins or a possible common evolutionary origin. The difference in peptide maps between the immunoprecipitated brain polypeptides and spectrin does, however, exclude the possibility of contamination by erythrocyte spectrin in the brain protein.

Spectrin analogue has similar morphology to erythrocyte spectrin

Erythrocyte spectrin is distinctive in that the tetramer appears in rotary-shadowed preparations as a highly extended rod almost 200 nm long¹¹. In similar preparations, the brain protein also appears as an extended rod with average length 195 nm and width 4–6 nm (estimated without compensating for the

additional mass of platinum) (Fig. 4). Occasionally, the rods open in the middle to reveal two parallel chains. The chains are most often closely apposed or helically entwined along the length of the molecule. Pig erythrocyte spectrin tetramers are slightly shorter with an average length of 175 nm, but otherwise are quite similar to the brain protein (Fig. 4). One significant difference between the two proteins is that, on average, the brain protein is straighter and there are fewer cases of separation of individual chains than observed for erythrocyte spectrin (Fig. 4A; compare with ref. 11). A more rigid conformation for the brain protein tetramer is indicated also by its lower sedimentation coefficient (10.8S) compared with that of the spectrin tetramer (12.5S). The brain protein tetramer was not converted to dimer by warming at 37°C (not shown) and thus is more stable than tetramers of erythrocyte spectrin. However, a limited conversion of tetramer to dimer was achieved by prolonged exposure to 1 M NaBr (Fig. 4). The dimers produced by this treatment exhibit a R_s of $\sim 110 \text{ \AA}$ and are comparable in length to erythrocyte spectrin dimers.

An important similarity between brain and erythrocyte proteins is that at concentrations less than 2 mg ml^{-1} , oligomers larger than tetramers were observed only rarely. Thus, it is likely that dimers of the brain protein have a polarity and are associated head-to-head, as has been suggested for erythrocyte spectrin^{11,27,28}. Otherwise, with a non-polar or a head-to-tail association, polymerization could occur to form extended filaments.

The spectrin analogue binds to erythrocyte membranes and to F-actin

Important criteria for a spectrin-like protein, in addition to structural similarities, are functions of binding to membranes and association with actin filaments. The brain protein remains

Fig. 2 Polypeptides (265K and 260K) cross-reacting with anti-spectrin antibody are localized in plasma membranes of liver. Plasma membrane sheets from blancher livers were isolated by two steps of upward flotation through 1.42 M sucrose essentially as described elsewhere⁴⁰ except that the buffers contained 7.5 mM sodium phosphate, 1 mM $MgCl_2$ pH 7.5, and protease inhibitors (200 $\mu g\ ml^{-1}$ PMSF and 0.01% (v/v) diisopropylfluorophosphate). Mitochondria were isolated as described elsewhere⁴¹ with the same buffer and protease inhibitors as above. The total microsomal and soluble fractions were isolated by pelleting (200,000g, 45 min) the 25,000g supernatant from liver homogenized in 0.25 M sucrose, 7.5 mM sodium phosphate, 1 mM $MgCl_2$ pH 7.5 and protease inhibitors. The microsomal pellet was washed once in 7.5 mM sodium phosphate, 1 mM Na-EGTA pH 7.5. Nuclear membranes were prepared essentially by the procedure of Dwyer and Blobel⁴² except that 0.5 mM Na-EGTA and protease inhibitors were included in the buffers, and the nuclei were digested with RNase and DNase. The samples were analysed on SDS-polyacrylamide gels; polypeptides were visualized by staining with Coomassie blue (CB; left) and immunoreactive polypeptides (right) identified as described in Fig. 1 legend. a, Erythrocyte ghosts; b, plasma membranes; c, microsomal membranes; d, nuclear envelopes; e, mitochondria; f, soluble proteins.

associated with membranes during repeated washes, and presumably is involved in a stable linkage with some membrane component(s). The brain protein also contains a binding site for erythrocyte ankyrin, as it displaces binding of ^{125}I -labelled erythrocyte spectrin to inside-out spectrin-depleted vesicles from erythrocyte membranes (Fig. 5). This assay measures association of spectrin with ankyrin, as spectrin binding to the membrane is displaced entirely by a spectrin-binding proteolytic fragment of ankyrin²⁹ and by antibody against this fragment of ankyrin¹². The brain protein is less active than erythrocyte spectrin, with 50% displacement at 60 nM compared with 30 nM for erythrocyte spectrin dimer. ^{125}I -labelled brain protein associates with erythrocyte membrane vesicles (not shown); this binding is blocked by unlabelled erythrocyte spectrin with 50% displacement at 10–15 nM (Fig. 5). The brain protein and erythrocyte spectrin thus bind to the same membrane site but erythrocyte spectrin binds with approximately twofold higher affinity. The lower affinity of the brain protein may be explained by a difference in its ankyrin-binding site, and/or may be a consequence of steric restrictions resulting from its more rigid conformation.

The brain protein associates with actin filaments, as demonstrated by co-sedimentation with actin through sucrose barrier gradients (Fig. 6). Over 60% of the brain protein was pelleted in the presence of actin, compared with <7% in the absence of actin, in conditions of 60 nM brain protein and 5 μM actin monomer. The brain protein greatly increased the low-shear apparent viscosity of F-actin, with an apparent gel point in the range of 60 nM (Fig. 6). Pig erythrocyte spectrin (tetramer/dimer ratio of ~3) exhibited a comparable activity (Fig. 6). The gel point for the brain protein varied with the actin preparation used and was as low as 20 nM when tested with actin purified further by gel filtration (V. Fowler, unpublished data).

Previous studies of cross-linking of actin filaments by human erythrocyte spectrin have noted the requirement for band 4.1 (refs 9, 10). We have also observed that human spectrin alone is not active in cross-linking actin, but that pig erythrocyte spectrin purified in the same way and compared in the same assay is not dependent on band 4.1 (V. Fowler and V.B., unpublished data). The results with pig spectrin agree with those of Brenner and Korn⁸ who observed that pure sheep erythrocyte spectrin was also capable of cross-linking actin

Fig. 3 Two-dimensional maps of ^{125}I -labelled α -chymotryptic peptides from α - (A–C) and β - (D–F) subunits of brain spectrin (A, D), brain spectrin immunoprecipitated by anti-erythrocyte spectrin antibody (B, E) and pig erythrocyte spectrin (C, F). ^{125}I -labelled brain spectrin (Fig. 1; 4×10^7 c.p.m.), ^{125}I -labelled brain spectrin immunoprecipitated by antibody against erythrocyte spectrin (Fig. 1; 2×10^6 c.p.m.) and pig erythrocyte spectrin (3×10^7 c.p.m.) were mixed with 2 μg unlabelled brain spectrin or erythrocyte spectrin and then electrophoresed on a SDS-polyacrylamide gel (see Fig. 1 legend). The gel was stained lightly with Coomassie blue, and equilibrated with 50 mM ammonium acetate, 1 mM sodium azide, pH 7. The protein bands were excised, suspended in 0.5 ml ammonium acetate buffer and incubated at 37 °C for 20 h with two additions of 25 μg α -chymotrypsin. The digests were lyophilized, and analysed by electrophoresis and chromatography as described elsewhere^{22,43}.

Fig. 4 Electron micrographs of rotary-shadowed brain spectrin (A, B and top row of C) and pig erythrocyte spectrin (bottom row of C). A, representative field of purified brain spectrin molecules which were diluted to $10 \mu\text{g ml}^{-1}$ in 100 mM ammonium formate (pH 7), mixed with 1/3 vol of glycerol, sprayed on to mica, dried under vacuum at room temperature and rotary-shadowed with platinum at an angle of 1 in 10 (refs 11, 44). Scale bar, 200 nm. B, brain spectrin molecules from a different less pure preparation, which was treated with 1 M NaBr for several days before dialysis against 100 mM ammonium formate and rotary shadowing as described for A; the field on the left includes an 'octamer' and two 'dimers', as well as two 'tetramers'. The two-stranded character of the molecules is seen more clearly in the field on the right and in C. Scale bar, 200 nm. C, selected brain spectrin molecules are shown in the top row and pig erythrocyte spectrin tetramers in the bottom row. These molecules were selected to demonstrate structural similarities between the two spectrin species, such as their two-stranded, double-helical nature. Scale bar, 200 nm.

filaments. Overloaded gels of brain spectrin exhibited contaminating polypeptides, but each polypeptide contributed no more than 1–2% of the total protein. Furthermore, the contaminating polypeptides were not specifically adsorbed by F-actin (Fig. 5). It is therefore unlikely that additional proteins are required in a 1:1 ratio with spectrin for association of brain spectrin with actin. The possibility that a protein may act in sub-stoichiometric ratios cannot be excluded.

Discussion

Here we have described the purification from brain membranes of an immunoreactive analogue of erythrocyte spectrin which closely resembles spectrin in structure and shares functions of binding to erythrocyte membranes and to actin filaments. The brain analogue of spectrin comprises 3% of the total membrane protein, and it would be surprising if this protein had not been noticed previously. An actin-binding protein containing two polypeptides of molecular weight ~240K and 235K has been purified partially from brain and has been termed brain actin-binding protein³⁰. An axonally transported protein with two polypeptide chains of molecular weight ~250K and 240K has been isolated from the particulate fraction of brain, and demonstrated to bind to actin³¹. This protein was named fodrin and was localized by immunofluorescence in the cortical cytoplasm of cultured fibroblasts, neurones and intestinal epithelial cells. It was concluded that fodrin was not related to spectrin as antibody against fodrin did not form a precipitin reaction with erythrocyte spectrin. However, this result does not exclude cross-reactivity that is partial or of reduced affinity.

It is possible that several groups have discovered the same protein and named it differently. We suggest that, in view of the similarity to erythrocyte spectrin, this protein be referred to as brain spectrin. Polypeptides of similar molecular weight to brain spectrin which cross-react with spectrin antibody are present in liver plasma membranes (Fig. 2) and membranes from other tissues (not shown). These proteins are probably also spectrin analogues and can be named according to the cell or tissue of origin.

The extent of structural homology between erythrocyte spectrin and the brain analogue is of the order of 20% as determined by immunoreactivity (Fig. 1). This is much less than the homology observed in other families of proteins such as actins, calmodulins and intermediate filament polypeptides. It should be kept in mind that spectrin polypeptides are unusually large and a homologous region could have a molecular weight of as

much as 60,000. Furthermore, the extended rod-like conformation of spectrin may be compatible with more variation in amino acid sequence than the folding of a globular protein. It is pertinent in this regard that peptide maps of erythrocyte spectrin from different species are substantially different (see above), even though the proteins are almost identical in morphology. In view of these considerations and the demonstration of functional homology, we suggest that the spectrins are a multigene family of proteins with a common evolutionary origin. Erythrocyte spectrin is probably the most deviant member of

Fig. 5 Displacement of binding of ^{125}I -labelled erythrocyte (—) and brain (---) spectrin to spectrin-depleted erythrocyte membranes by unlabelled erythrocyte (●) and brain (○) spectrin. Binding of ^{125}I -labelled erythrocyte spectrin dimer (1 nM , $2 \times 10^6 \text{ c.p.m. pmol}^{-1}$) and ^{125}I -labelled brain spectrin (1 nM , $8 \times 10^5 \text{ c.p.m. pmol}^{-1}$) to spectrin-depleted inside-out vesicles from human erythrocytes ($20 \mu\text{g}$ membrane protein per assay) was measured as described elsewhere⁴⁵, in the presence of increasing concentrations of unlabelled brain spectrin (○) and pig erythrocyte spectrin dimer (●). The data are expressed as per cent binding in the absence of added proteins, and are corrected for nonspecific binding at each concentration of unlabelled proteins by subtracting values for ^{125}I -labelled proteins that were heat-denatured (10 min at 70°C).

Fig. 6 Brain spectrin co-sediments with F-actin and increases the low-shear viscosity of F-actin. Brain spectrin ($60 \mu\text{g ml}^{-1}$) was incubated (60 min at 30°C) in the presence or absence of rabbit muscle actin⁴⁶ ($200 \mu\text{g ml}^{-1}$) in buffer containing 40 mM PIPES pH 6.8, 20 mM KCl, 1 mM MgCl_2 , 5 mM Na-EGTA. The proteins were layered over 10% (w/v) sucrose in the same buffer and centrifuged at $200,000g$ for 60 min. The pellets were resuspended in the original volume, and equal aliquots of pellets and supernatants analysed by SDS-polyacrylamide gel electrophoresis (see Fig. 1). The polypeptides were visualized with Coomassie blue, and the gels were scanned in a densitometer (left): A, pellet, brain spectrin and actin; B, supernatant, brain spectrin and actin; C, pellet, brain spectrin alone; D, supernatant, brain spectrin alone. E, effect of increasing concentrations of brain spectrin (\circ) on the low-shear viscosity of actin (0.8 mg ml^{-1}) was determined in the same buffer with a falling ball viscometer^{10,47}. For comparison, pig erythrocyte spectrin (tetramer/dimer ratio = 3) was tested in the same assay (\bullet). In the absence of actin the proteins had very low viscosity (---).

this family, as the functional constraints in these specialized cells are quite different from those in more complex cell types.

The widespread distribution of spectrins implies that functional analogues of ankyrin and band 3 should also be present in other cell types. A polypeptide of $M_r \sim 200,000$ that cross-reacts with antibody against ankyrin is associated with membranes of brain and the plasma membrane fraction of liver (not shown; ref. 32). Immunoreactive forms of band 3, detected with antibody against the cytoplasmic domain of band 3, are also present in the same membrane fractions as ankyrin and spectrin (not shown). It will be essential to purify and characterize these cross-reacting polypeptides to verify possible functions.

Spectrin in association with actin and band 4.1 forms a supportive lattice on the inner surface of the plasma membrane in erythrocytes, and spectrin may also participate in a similar structure in plasma membranes of other cells. Actin is associated with a detergent-insoluble matrix underlying the plasma membrane^{33,34}, and has been identified in association with the inner surface of the plasma membrane in several cases¹. Cells in tissues also have specialized regions of cell-cell contact such as zonula adherens and postsynaptic densities where actin filaments are attached to the membrane. Spectrin may function in these areas to couple actin to the membrane and to form a two-dimensional meshwork adjacent to the membrane analogous to the matrix in erythrocytes.

The spectrins are large enough to be visualized by high resolution electron microscopy of cells and tissues, and would appear as flexible filaments 2–4 nm wide. Filaments having these dimensions and lengths up to 300 nm have been observed in whole mounts of cells by high voltage electron microscopy

and seem to link actin to other cell structures³⁵. Filaments 4 nm wide have also been reported in postsynaptic densities—these were visualized by rapid freezing and rotary shadowing³⁶, and appear to interact with actin filaments as well as intramembrane particles. The narrow filaments do not correspond to previously studied structural proteins and may, at least in part, be composed of spectrin.

The widespread distribution of proteins closely related to erythrocyte spectrin and possibly other erythrocyte proteins suggests it will soon be possible to define in detail at least one generally occurring type of linkage of actin filaments to membranes. This information may explain how integral membrane proteins are organized and directed in their motions and will also be important in understanding how membranes are integrated with the cytoplasm.

Following submission of this article, a protein of similar structural features to brain spectrin has been purified from brain and intestine³⁷. Immunoreactive forms of spectrin and their distribution have also been observed in several tissues³⁸. A brain protein having similar properties to brain spectrin has been isolated³⁹.

This research was supported by grants to V.B. from the NIH (1 RO1 AM29808-1 and a Research Career Development Award) and the Muscular Dystrophy Association. W.E.F. was supported by a postdoctoral fellowship from the Muscular Dystrophy Association. Facilities for electron microscopy were funded in part by grants to Dr Ueli Aepli from the Muscular Dystrophy Association and the NIH (GM2-7765). We thank Drs Ann Hubbard and Larry Gerace for advice on the preparation of plasma membranes and nuclear envelopes from liver. Dr V. Fowler provided muscle actin and advice on measurement of low-shear viscosity.

MERLIN spectral line observations of circumstellar shells around two OH/IR stars

R. P. Norris, P. J. Diamond & R. S. Booth

University of Manchester, Nuffield Radio Astronomy Laboratories, Jodrell Bank, Macclesfield, Cheshire SK11 9DL, UK

The OH maser emission from OH/IR stars shows structure on an arc second scale, and is therefore ideally suited to observation by the new Jodrell Bank Multi Element Radio Linked Interferometer Network (MERLIN)¹ operating in the spectral line mode². Here we present MERLIN observations of two OH/IR stars: OH127.8–0.0 and OH104.9+2.4. The spatial structure of OH127.8–0.0 revealed by Booth *et al.*³ using three single base line interferometers was consistent with a simple expanding shell model. Our maps of OH127.8–0.0 confirm this interpretation, whereas the circumstellar shell that we find around OH104.9+2.4 exhibits a more complex motion, which we interpret in terms of rotation.

The sources OH127.8–0.0 and OH104.9+2.4, hereafter called OH127.8 and OH104.9 respectively, were observed at 1612.231 MHz with four telescopes of MERLIN in March 1981. The measured cross-correlation functions on the six baselines were recorded every 30 s and then Fourier transformed off-line to yield a spectrum of 80 frequency channels on each baseline. The unresolved source BL Lac was also observed to calibrate and correct the data for both amplitude and phase variations across the bandpass. During the observations on each source, additional phase variations occur which are common to all channels. These are corrected as follows.

The emission in one channel, the reference channel, containing strong emission which need not be spatially simple or unresolved was mapped using the closure phase technique⁴. The resulting spatial distribution was then Fourier transformed to obtain ϕ_{ss} , the phase due to the source structure. The phases ϕ in the other frequency channels were then corrected using the relation

$$\phi' = \phi - \phi_{ref} + \phi_s - \phi_{BP}$$

where ϕ_{ref} is the observed phase of the reference channel and ϕ_{BP} is a small correction term describing the phase response of the instrument. The corrected phases ϕ' and the observed amplitudes were processed using the CLEAN algorithm⁵ to produce maps of the brightness distribution integrated over suitable velocity intervals.

The OH maser emission from OH/IR stars is characterized by a double-peaked spectrum, demonstrated by Fig. 1a, which

shows the autocorrelation spectrum of OH127.8. Neither OH127.8 nor OH104.9 have been detected optically, but they have been identified with the IR sources CRL230 and CRL2885 respectively. The stellar velocity is assumed to lie roughly at the midpoint of the velocities of the OH maser peaks, and the double-peaked spectrum may then be produced by expansion, contraction or rotation of circumstellar material containing the OH.

By analogy with OH/IR stars which do have optical identifications, the central star is probably an *M* giant star, but its mass may lie anywhere in the range from $\sim 1 M_{\odot}$, corresponding to a Mira variable, to $\sim 30 M_{\odot}$, corresponding to an *M* supergiant.

Figure 1a demonstrates that the flux density has decreased by approximately a factor of 3 compared with that measured in 1980³. Such variations in intensity are well known in OH/IR

Fig. 1 Autocorrelation spectrum of: a, OH127.8; b, OH104.9 measured in July 1981.

Fig. 2 Maps of the emission in each of the 12 frequency channels shown in Fig. 1a. The lowest contour level and the contour spacing are 0.1 Jy per beam area, except for maps *k* and *l* in which the lowest contour level is 0.3 Jy. Map *l* is the reference feature mapped using the closure phase technique. Only the lowest 10 contours are shown in each case.

stars^{6,7}. Unfortunately, this reduction in brightness precludes our detecting the weaker emission detected by Booth *et al.*, preventing a detailed correspondence between the two sets of maps.

Also shown in Fig. 1a are 13 velocity ranges. Each of the maps in Fig. 2 represents the spatial distribution of the masing gas within the corresponding velocity interval in Fig. 1a. These maps have greater frequency resolution than those published by Booth *et al.*³ and confirm their earlier interpretation. The similarity of these maps to those of Booth *et al.*, despite the variation in intensity, confirms that the variations are a result of changes in the brightness of the star's IR radiation which

pumps the OH masers, rather than changes within the masing gas.

The maps show that the emission at each of the two ends of the spectrum emanates from two spatially coincident compact regions at the centre of the source, whilst the weaker emission towards the centre of the spectrum shows a roughly annular distribution. The radii of the annuli increase with decreasing velocity separation from the centre of the spectrum, in the way expected for a uniformly expanding shell of OH. The knots and gaps in the annuli indicate some turbulence or inhomogeneities in the expanding shell.

The spectrum of OH104.9, shown in Fig. 1b has a similar

Fig. 3 Maps of the emission in each of the 12 frequency channels shown in Fig. 1b. The lowest contour level and the contour spacing are 0.5 Jy per beam area. Contours above a flux density of 10 Jy have been suppressed.

overall form to that of OH127.8 but is not as smooth and indicates a more complex motion. This is reflected in the maps shown in Fig. 3 in which no complete annuli are observed. However, the strong emission at each end of the spectrum again emanates from a region close to the centre of the source.

Note that there is no detectable emission in a region to the west of the source. However, because the maser requires a uniform line of sight velocity along its length, the maser process is extremely sensitive to inhomogeneities and anisotropies in the gas dynamics. Therefore the absence of emission may be explained as a random perturbation or non-uniformity in the gas dynamics. Such irregularities have already been seen in OH26.5 (ref. 9).

Relative RA (arc s)

A detailed study of the components in the maps shows a further systematic departure from a simple expanding shell model. For example, in the regions to the north and south of the centre, components in the front and back of the shell which appear spatially coincident have a mean velocity of -25.8 km s^{-1} , whereas similarly coincident components to the east have a mean velocity of -25.3 km s^{-1} .

For a uniformly expanding shell, the radius $a(v)$ at which the line of sight component of the expansion velocity is v is given by

$$a(v) = R[1 - (v/v_e)^2]^{1/2}$$

where v_e is the expansion velocity and R is the shell radius.

Table 1 Parameters of the model for OH127.8 and OH104.9

	OH127.8	OH104.9
RA of centre relative to coordinate centre (arc s)	-0.11 ± 0.01	-0.12 ± 0.01
Dec. of centre relative to coordinate centre (arc s)	-0.15 ± 0.01	-0.21 ± 0.01
Position angle of rotation axis (deg)	10 ± 5	0 ± 5
Stellar velocity relative to the local standard of rest (km s^{-1})	-55.4 ± 0.2	-25.8 ± 0.2
Expansion velocity (km s^{-1})	10.9 ± 0.2	14.3 ± 0.2
Rotation velocity (km s^{-1})	0.2 ± 0.1	-0.9 ± 0.1
Shell radius (arc s)	1.53 ± 0.02	1.44 ± 0.02

These values assume that the rotation axis is perpendicular to the line of sight, because the fit is insensitive to this parameter. The quoted errors are estimated 1σ uncertainties.

For material in a uniform expanding shell, therefore, a plot of $\log a$ against $\log[1 - (v/v_e)^2]$ should yield a straight line with a gradient of 0.5. A plot of these quantities for some of the components of OH104.9 is shown in Fig. 4. The components to the north and south of the centre follow the uniform expanding shell model, but the components to the east, which are shown in Fig. 4, do not. Departure from a gradient of 0.5 may be caused either by an error in the assumed position of the expansion centre or by an incorrect value of v_e . Similarly, separation on the plot of high and low velocity components which are spatially coincident may be caused by an incorrect value of the central (stellar) velocity. However, even if all these parameters are allowed to vary, there is still no solution for a uniformly expanding, non-rotating shell which fits all the observed data.

We conclude that the kinematics of the components depart from a simple expanding shell model not only because of small-scale turbulence as mentioned above, but also because of a large scale non-radial motion. The simplest explanation of the non-radial motion is that the shell is rotating about the star as well as expanding from it. The kinematics of a rotating, expanding, thin shell are easily modelled and we have used a computer least squares program to fit such a model to the data on OH127.8 and OH104.9, resulting in the parameters given in Table 1. In each case, there is excellent agreement between the model and the data, and the r.m.s. error in velocity is $\sim 0.3 \text{ km s}^{-1}$, which is less than half our velocity resolution of 0.8 km s^{-1} . The model for OH127.8 shows no significant rotation, but the shell around OH104.9 is rotating with an equatorial speed of 0.9 km s^{-1} .

Fig. 4 A plot of $\log_{10} a$ against $\log_{10}(1 - (v/v_e)^2)$ for components at position angle 90° (see text). Line B is the curve expected from a simple expanding shell model. Lines A and A' are the curves expected from a rotating expanding shell. ●, The observed data, and the arrows connecting them are in the direction of increasing velocity. Despite the large scatter in the data points, they show clearly the bifurcation expected from a rotating expanding shell. Small letters against data points correspond to the maps in Fig. 3.

The angular momentum of the shell may be derived either from rotation of the star or from the orbital angular momentum of a binary companion. The former explanation implies a high rate of angular momentum loss from the star, leading us to favour the second explanation. A plausible model would separate the binary companion from its primary by $\sim 10^{15} \text{ cm}$, implying an orbital period of the order of hundreds of years. The current position of the companion, which may destroy the conditions for maser emission, may lie to the west of the source, where there is no detectable OH maser emission. These models are developed and discussed in more detail in ref. 10.

The evaluation of the mass loss rate from long period variable stars is of great importance in understanding stellar evolution. By assuming³ a molecular hydrogen number density of $2 \times 10^4 \text{ cm}^{-3}$, we derive a mass loss rate of $8 \times 10^{-5} M_\odot \text{ yr}^{-1}$ for OH127.8 and $5 \times 10^{-5} M_\odot \text{ yr}^{-1}$ for OH104.9. Such high mass loss rates agree well with the IR properties of OH/IR stars¹¹, although they imply a short lifetime for a star in this state.

We have produced further evidence for the evidence of a simple expanding shell around OH127.8, and have shown that OH104.9 possesses a shell which is rotating as well as expanding, and may be a member of a binary system. It is clearly necessary to extend these results to other sources, and such work is in progress.

Ion nucleation—a potential source for stratospheric aerosols

F. Arnold

Max-Planck-Institut für Kernphysik, Postfach 103 980, 6900 Heidelberg, FRG

The stratospheric aerosol layer is of considerable interest for its potential influence, at least temporarily, on the Earth's radiation budget and climate¹. While the nature of the aerosol is now reasonably well established the mechanisms leading to the formation of new particles are poorly understood^{2–4}. It is thought that the aerosols are formed by heterogeneous heteromolecular condensation involving sulphuric acid and water vapour and pre-existing condensation nuclei (CN) of tropospheric or meteoric origin. The resulting supercooled solution droplets which are composed of $\sim 75\%$ (by mass) H_2SO_4 and 25% H_2O undergo condensational and coagulational growth and are ultimately removed from the stratosphere by gravitational sedimentation. CN-formation in the stratosphere by homogeneous or ion nucleation (IN) has largely been found to be inefficient^{2–6}. I have now investigated the role of recent progress in both the areas of stratospheric ion composition⁷ and sulphuric acid vapour^{8–10} measurements. In contrast to previous conclusions ion nucleation is found to be a potential source for stratospheric aerosols.

Ion nucleation involves growth of ions by association of gas molecules to a critical size at which the resulting molecular cluster is stable against evaporational destruction after neutralization of its net charge by ion-ion recombination. In

Fig. 1 Typical time scales for ion growth (t_A), ion-ion recombination (t_R), H_2SO_4 attachment to ions (t_I) and aerosols (t_{AE}) and vertical turbulent transport (t_T). For t_A two cases, H_2SO_4 - H_2O aerosols ($^1t_{AE}$) and, in addition to these, meteoric smoke particles ($^2t_{AE}$) (7% recondensation of meteor vapour) are given¹⁷. For details see text. For t_R evaluation measured α and n_{\pm} values were taken.

stratospheric conditions only molecular clusters containing H_2SO_4 and H_2O molecules can form CN. Consequently only ions containing H_2SO_4 and H_2O molecules can be involved in IN. It has been found recently⁷ from balloon-borne composition measurements of stratospheric negative ions that the most abundant ion species above 27 km are H_2SO_4 (H_2SO_4) $_n$ (H_2O) $_m$ and that these already develop properties similar to H_2SO_4 - H_2O solution droplets for $n \geq 3$. The time scale for addition of an H_2SO_4 molecule to an ion is $t_A = (k[H_2SO_4])^{-1}$ where k is a phenomenological binary rate coefficient for H_2SO_4 association being typically of the order of $10^{-9} \text{ cm}^3 \text{ s}^{-1}$ in the conditions considered^{11,12} and $[H_2SO_4]$ is the concentration of H_2SO_4 -vapour molecules.

The ion lifetime compared with ion-ion recombination is $t_R = (\alpha n_{\pm})^{-1}$ where α is the effective ion-ion recombination coefficient and n_{\pm} is the total charged particle concentration.

The abundance ratio $R_{n+1,n}$ for ions containing $n+1$ and n H_2SO_4 molecules is obtained from a simple steady state treatment

$$R_{n+1,n} = (1 + t_A/t_R)^{-1} \quad (1)$$

accordingly one obtains the approximation

$$R_{n_c,0} = (1 + t_A/t_R)^{-n_c} \quad (2)$$

where n_c is the number of H_2SO_4 molecules contained in an ion cluster which also remain stable against evaporational destruction after neutralization.

Thus the ion nucleation rate is

$$J = Q(1 + t_A/t_R)^{-n_c} \quad (3)$$

where Q is the galactic cosmic ray ionization rate, being of the order of $10 \text{ cm}^{-3} \text{ s}^{-1}$ in the middle stratosphere¹³.

The critical quantity n_c may be set equal to the number of H_2SO_4 molecules contained in an electrically neutral drop which is just stable and whose size may be obtained from the Kelvin expression¹⁴. The latter relates the droplet radius r_c to the supersaturation ratio $S = p/p_0$ where p and p_0 are the partial and equilibrium saturation pressures for sulphuric acid vapour. For $S \leq 6$, n_c becomes larger than ~ 10 and increases steeply as S increases. This is consistent with laboratory studies¹⁵ of IN suggesting that IN becomes efficient for $S \geq 4-6$. However, usually in these studies $t_A \ll t_R$, in contrast to the stratospheric situation.

Typical t_A and t_R values are shown in Fig. 1. Measured α and n_{\pm} were taken (ref. 16, and D. Smith, personal communication) and k was set equal to $10^{-9} \text{ cm}^3 \text{ s}^{-1}$. Values for $[H_2SO_4]$ were taken from recent measurements⁸⁻¹⁰ (Fig. 2) where it was

found that $[H_2SO_4]$ below ~ 27 km is similar to the lower limit curve predicted by the theoretical model case of Turco *et al.*¹⁷ which neglects H_2SO_4 re-evaporation from the aerosol. Above ~ 35 km, $[H_2SO_4]$ is similar to the upper limit curve CHA 75) predicted by a purely photochemical diffusive model¹⁸ which neglects H_2SO_4 condensation. In the intermediate altitude range (27-35 km) $[H_2SO_4]$ is similar to $[H_2SO_4]_e$, the expected equilibrium saturation pressure for H_2SO_4 over the aerosol^{9,10}.

Thus it appears that $S < 1$ above ~ 35 km, $S = 1$ between ~ 27 and 35 km and $S > 1$ below ~ 27 km. That implies that aerosols are unstable above ~ 35 km and that IN can occur only at heights below ~ 27 km. Since $[H_2SO_4]_e$ increases strongly as temperature increases, the $[H_2SO_4]_e$ curves are different for winter and summer due to seasonal temperature changes. Corresponding $[H_2SO_4]_e$ curves for winter (45 W) and summer (45 S) and 45° latitude are also shown in Fig. 2.

Ion nucleation rates J calculated from equation (3) for average winter and summer temperatures at 45° latitude are shown in Fig. 3. Here the curve T80 (Fig. 2) was taken as a lower limit to $[H_2SO_4]$.

Generally the calculated J values increase as height increases and decrease abruptly above a certain height where S becomes smaller than ~ 10 and where consequently n_c becomes large. This is due to the large t_A/t_R ratios in this height region. Maximum J values of about $3 \times 10^{-3} \text{ cm}^{-3} \text{ s}^{-1}$ (winter) and $5 \times 10^{-4} \text{ cm}^{-3} \text{ s}^{-1}$ (summer) are reached around 29 km and 24 km respectively. Corresponding column IN rates J_c are $\sim 9.3 \times 10^2 \text{ cm}^{-2} \text{ s}^{-1}$ (winter) and $1.6 \times 10^2 \text{ cm}^{-2} \text{ s}^{-1}$ (summer). By comparison, the globally averaged J_c required to maintain the stratospheric aerosol layer is only of the order of $0.01 \text{ cm}^{-2} \text{ s}^{-1}$.

Thus IN apparently has the potential to form more CN than required to seed the stratospheric aerosol layer.

However, a large fraction of the newly formed CN may become removed before they can grow a new aerosol solution droplet. Loss processes may involve mostly CN attachment to aerosols. The lifetime of a gas molecule (molecular weight 29) against collision with aerosols t_{AE} is given in Fig. 1. Below 30 km it is of the order of only 10^4 - 10^5 s. In comparison, the time scale for adding an H_2SO_4 -gas molecule to a CN having a radius of 10^{-7} cm is of the order of 10^4 s. Thus a newly formed CN can pick up a few more H_2SO_4 -vapour molecules before it collides with an aerosol solution droplet. This is particularly true as the CN lifetime against collision with aerosols should be much larger than t_{AE} due to the large CN mass.

Fig. 2 Sulphuric acid vapour concentrations. Measured values⁸⁻¹⁰ are indicated by the shaded area. Extreme cases as obtained from theoretical model calculations are indicated by H75 (all sulphuric acid in the gas phase¹⁷) and T80 (no re-evaporation of sulphuric acid vapour¹⁶) for average winter and summer temperatures at 45° latitude are also shown.

Fig. 3 Calculated ion nucleation rates J : a , average winter temperatures (T_w); b , average summer temperatures (T_s); c , cooling from T_s to T_w ; d , cooling from $T_s + 5$ to T_s ; e , cooling from $T_s + 10$ to T_s .

Assuming a CN lifetime against attachment to aerosols of 10^5 s and a yearly averaged J of the order of 10^{-3} $\text{cm}^{-3} \text{s}^{-1}$ around 25–30 km one obtains an average CN concentration $[\text{CN}]$ of the order of 100 cm^{-3} for the 25–30-km region and 10 cm^{-3} for 20 km.

Measured¹⁹ $[\text{CN}]$ are about $1\text{--}100 \text{ cm}^{-3}$ (25–30 km) and $1\text{--}10 \text{ cm}^{-3}$ (20 km) and compare reasonably well with the above model predictions for altitudes below about 25–30 km.

However, no CN formation occurs above 25–30 km in the conditions considered and therefore CN must be transported, mostly by turbulent diffusion, to this height range. The time scale for vertical turbulent diffusion t_T (per kilometre) is given in Fig. 1, being $\sim 10^5\text{--}10^6$ s (1–10 days). Thus it is much larger than the CN lifetime against collision with aerosols, which implies that little vertical CN transport should occur below ~ 35 km. Consequently, CN observed above 25–30 km can hardly be explained by the above IN model.

In the stratosphere, however, dramatic departures from a condensation–evaporation equilibrium for sulphuric acid can occur. These should be induced by short-term temperature changes which are quite common, particularly at latitudes $>45^\circ$ during local winter²⁰. An example of temperature changes at 35 km in Fig. 4 shows measured temperatures along with average summer (S), spring–autumn (SA) and winter (W) values. Typical amplitudes and time scales are about $5\text{--}10^\circ$ and one to a few days respectively in winter; occasionally, dramatic temperature enhancements, ‘sudden stratospheric warmings’, occur²⁰ during which temperatures may even exceed summer values. These events are thought² to arise mostly from large amplitude planetary waves pumping heat energy from the tropical troposphere and stratosphere to the polar regions. Thus, the radiative imbalance in the atmosphere arising from the smaller amount of solar radiation absorbed at high latitudes is compensated through adiabatic processes.

As the temperature increases, $[\text{H}_2\text{SO}_4]$ increases (by about a factor of 10 per 10° (refs 22, 23). Eventually the entire $\text{H}_2\text{SO}_4\text{--H}_2\text{O}$ aerosol may evaporate, depending on the maximum temperature reached, in which case $[\text{H}_2\text{SO}_4]$ would be equal to curve H75 (Fig. 2). As the temperature falls again, sulphuric acid vapour may become highly supersaturated with respect to the condensed $\text{H}_2\text{SO}_4\text{--H}_2\text{O}$ phase.

The time scale for H_2SO_4 -vapour recondensation on aerosols is larger than t_{AE} (Fig. 1), being ~ 1 day around 30 km. This implies that high supersaturations may persist for at least 1 day.

A typical case for a major winter warming would be a temperature rise to average summer values and a subsequent cool-

ing to average winter values which implies a maximum S of ~ 3 (Fig. 2). Corresponding J values are shown in Fig. 3 (curve c). Around 35 km they become comparable to Q ($10 \text{ cm}^{-3} \text{s}^{-1}$) and fall off steeply above and less steeply below this height. The thickness of the IN layer is ~ 5 km. The fall-off towards larger heights is mostly due to a decrease of S causing a steep increase of n_c . The fall-off towards smaller heights is mostly due to the decrease of $[\text{H}_2\text{SO}_4]$ causing an increase of t_A/t_R .

Summer IN events for temperature increases of 5° and 10° and subsequent coolings to average summer values are also shown in Fig. 3 (curves d and e). These IN layers peak around 34 and 33 km respectively and are ~ 1.5 and 5 km thick respectively.

For curves c , d and e maximum J values are sufficiently large to allow for a rapid build-up of a limiting $[\text{CN}]$, being of the order of 10^5 cm^{-3} within <1 day. For $[\text{CN}] \geq 10^5 \text{ cm}^{-3}$ the lifetime of a CN against mutual CN coagulation becomes ≤ 1 day. For $[\text{CN}] = 10^5 \text{ cm}^{-3}$ the lifetime of an H_2SO_4 -vapour molecule against attachment to a CN is of the order of $10^4\text{--}10^5$ s. Consequently the supersaturated H_2SO_4 vapour should become consumed by condensation onto the newly formed CN within a day or less, leading to an average aerosol corresponding to only $10^3\text{--}10^4$ H_2SO_4 molecules or $\sim 4\text{--}8 \times 10^{-7}$ cm in radius.

In the days after their formation the CN undergo further mutual CN coagulation until $[\text{CN}]$ has fallen to a level of $\sim 10^3\text{--}10^4 \text{ cm}^{-3}$, at which the time scale for coagulation becomes weeks to months. At these time scales vertical turbulent diffusion becomes efficient, having a time scale t_T of the order of a few days per kilometre. Vertical turbulent diffusion leads to a broadening of the CN layer and a further decrease of the peak $[\text{CN}]$ value.

Upward diffusion carried the CN into a region where $S < 1$ leading to CN evaporation. Downward diffusion carries CN into a region of large S where they are safe from evaporational destruction by subsequent warming events.

It appears then that IN due to warming–cooling events is an efficient CN source at heights around 27–37 km. It may give rise to average $[\text{CN}]$ values of the order of $10^3\text{--}10^4 \text{ cm}^{-3}$, corresponding to average CN sizes of 1.6×10^{-6} cm and 8×10^{-7} cm respectively.

The column IN rates J_c corresponding to curves c , d and e (Fig. 3) are $\sim 4 \times 10^7 \text{ cm}^{-2} \text{s}^{-1}$, $1 \times 10^7 \text{ cm}^{-2} \text{s}^{-1}$ and $4 \times 10^7 \text{ cm}^{-2} \text{s}^{-1}$.

The column IN production for long-lived CN only (lifetime >1 day) are $\sim 6 \times 10^{10} \text{ cm}^{-2}$, $1 \times 10^{10} \text{ cm}^{-2}$ and $6 \times 10^{10} \text{ cm}^{-2}$. In comparison, the persistent IN source existing below

Fig. 4 Stratospheric temperatures (E. Pantzke, personal communication) as measured at 35 km altitude over Berlin (52°N , 14°E) during the winter 1975–76. Corresponding saturation concentrations for sulphuric acid vapour and average winter-, spring–autumn- and summer temperatures²⁴ are also given.

25–30 km leads to a column production of $\sim 2 \times 10^{10} \text{ cm}^{-2}$ for an entire year.

Thus the warming-cooling events contribute substantially to, or even dominate, the overall CN production. Regionally and during certain periods of time they give rise to large CN concentrations in the 27–37 km range.

Note that there is a possible influence of solar activity on the CN production by IN. Galactic cosmic radiation, the only important source of ionization in the undisturbed stratosphere, is partly shielded by the interplanetary magnetic field which gives rise to an anticorrelation of Q and solar activity. Typically Q values by about a factor of 4 over a solar sunspot cycle at middle latitudes. Since $n_{\pm} = (Q/\alpha)^{1/2}$, t_R varies by a factor of about 2. The t_R curve shown in Fig. 1 and used for the above calculations corresponds to solar sunspot maximum conditions (large t_R).

For solar sunspot minimum, t_R is smaller by a factor of 2, leading to smaller IN rates, particularly in conditions where $t_A/t_R \gg 1$. For example, the maximum value of curve a (Fig. 3) would be smaller for solar sunspot minimum conditions by about a factor of 10.

Thus the global CN production by IN may be substantially smaller during conditions of low solar activity. As a consequence the aerosol size distribution may shift towards larger sizes as fewer CN compete for the available sulphuric acid. As a change of the aerosol size distribution may affect the radiation properties of the stratospheric aerosol layer, solar activity changes may modulate the possible influence of the stratospheric aerosol layer on the Earth's radiation budget and climate.

Finally possibilities for observational tests of the ion nucleation hypothesis will be discussed. Observable quantities are [CN], [H₂SO₄] and the ion composition. Concerning [CN] the IN model seems to be in harmony with measurements. In particular the CN layer recently detected by Hofmann and Rosen¹⁹ around 30–35 km is readily explained and its major features are reasonably well reproduced by the IN model.

It seems, however, that predicted [CN] values are larger than observed ones. As far as [H₂SO₄] and ion composition measurements are concerned only few data exist. It would be desirable to carry out coordinated measurements of [CN], [H₂SO₄] and ion composition during a major winter warming-cooling event. During the early phase of the cooling large S values and very complex ion clusters should occur while large [CN] values should persist for days after the onset of the cooling.

Note that the above model calculations of IN are only rough approximations and that extensive model calculations of stratospheric IN should be carried out.

I thank D. J. Hofmann, P. Hamill, K. Labitzke and B. Naujokat for helpful discussions, and E. Pantzke for providing stratospheric temperature data.

Ozone vertical distribution and total content using a ground-based active remote sensing technique

J. Pelon & G. Megie

Service d'Aéronomie du CNRS, BP 3, 91370-Verrieres-Le-Buisson, France

The evaluation of possible perturbations of anthropogenic origin on the Earth environment has become increasingly important with the development of industrial and agricultural activities. Among these the depletion of the ozone layer under the influence of chemically active minor constituents produced by anthropogenic sources is still under question, thus emphasizing the importance of ozone monitoring in the atmosphere. Beside classical systems, such as the Dobson spectrometer and Brewer or ECC sondes, new techniques of ozone monitoring are being developed which include passive IR and microwave spectrometry and active IR and UV laser soundings¹. They should soon allow complementary routine measurements. We have previously described² the UV lidar system set up at the Observatoire de Haute Provence (44° N, 6° E) in the south of France and the methodology of the differential absorption laser technique (DIAL) which provide routine measurements of the ozone vertical distribution from the ground up to 25 km. We report here the first active ground-based measurements of the ozone distribution at higher altitudes up to 40 km and of the total ozone content using the same system.

Attempts to measure ozone number density above its maximum using a ground-based UV system are complicated because the extinction of the laser emitted light is high due to the absorption in the lower altitude layers. Furthermore the rapid decrease in ozone number density above 28 km requires very rapidly increasing acquisition times for the measurement². To overcome these major problems, a different wavelengths pair B (305.8–310.8 nm) was chosen to probe the upper levels (13–38 km) as compared with the one A (288.8–294.5 nm) previously adopted for the lower altitude range. These wavelengths choices minimize the interferences by other absorbing gases (SO₂–NO₂) and by aerosol particles and optimize the signal-to-noise ratio². Whereas ozone distribution measurements in the boundary layer can be performed using the DIAL method³, we have restricted our measurements to the altitude range above 3 km to avoid any problem related to geometrical effects and to the large dynamic of the backscattered signals in the first few kilometres. Compared with the previously reported measurements², a factor of 5 reduction in the acquisition time has been obtained by increasing the receiving telescope diameter from 36 to 80 cm. The parameters of the lidar system are listed in Table 1. Adopted values for the ozone absorption cross-sections are those of Inn and Tanaka⁴ corrected for temperature dependence as given by Vigroux⁵.

Figure 1 represents two lidar measured ozone profiles as obtained on 1 and 2 December 1981 at 00 h UT. The acquisition time for each profile is 90 min. The vertical resolution varies between 360 m in the troposphere, 1.2 km at 25 km and 3.6 km

Table 1 Parameters of the lidar system

Emitted wavelengths		
A pair	$\lambda_1 = 288.80 \text{ nm}$	$\lambda_2 = 294.50 \text{ nm}$
B pair	$\lambda_1 = 305.80 \text{ nm}$	$\lambda_2 = 310.80 \text{ nm}$
Spectral width $\Delta\lambda < 5 \text{ pm}$		
Emitted energy $E = 40 \text{ mJ-10 Hz}$		
Divergence $< 0.5 \text{ mrad}$		
Telescope $\phi 80 \text{ cm}$		
Field of view 0.7 mrad		

at 35 km and above. A moving parabolic least-square regression is used to fit the experimental data². The 1σ -standard deviation is better than 5% up to 25 km and decreases down to 20% at the uppermost level. To avoid systematic errors due to the aerosol particles extinction, the aerosol layers were detected by simultaneously recording the lidar backscattered signals at 532 nm. No enhanced aerosol layer was detected during these measurements and no further correction was performed on the 0.3- μ m lidar signals². As a comparison, the ozone distribution measured using a classical Brewer-Mast sonde launched by the Météorologie Nationale at Biscarrosse (44° N, 0.5° W) on 30 November at 13 h 30 UT is also shown in Fig. 1. The agreement between the various profiles can be considered as satisfactory above 20 km, only a systematic bias <1.5% between the Brewer and lidar measurements was detected. At lower altitudes the variations observed in the ozone number density can be attributed to horizontal inhomogeneities due to dynamical motions as they are frequently observed in this altitude range: a north-south circulation was established at the 100-mbar level over western Europe in early December⁶ which could explain the variations observed. In any case, previous comparisons of lidar and ECC measured ozone profiles below 25 km have shown the reliability of the DIAL remote sensing technique⁷.

Both wavelengths pairs A and B were used to measure the ozone number density between 13 and 15 km: considering several profiles obtained during successive nights a systematic bias was detected showing ozone values 2% higher when measured using the A pair. This discrepancy can be related (1) to uncertainties in the absolute values of the cross-sections and (2) to the very high spectral resolution of the laser measurements as compared with the spectrometric ones^{4,5}. Due to experimental uncertainties, the detected bias between the A, B pairs and Brewer measurements could only be considered as estimations in this first approach; as the overall bias was not larger than 2% no final adjustment was performed.

The total ozone content can be derived from the measured vertical distribution. Various sources of uncertainty then have to be considered²:

Fig. 1 Ozone concentration profiles measured by lidar at the OHP on 1 December 1981 (dashed line) and 2 (dotted line) at 0 h UT compared with the profile obtained by a Brewer sonde launched at Biscarrosse on 30 November 1981 at 13 h 30 UT (solid line).

Fig. 2 Total ozone measured by lidar at the OHP (dashed line) and Dobson spectrometers at Biscarrosse (solid line) and Arosa (∇).

- (1) The statistical fluctuations of the detected signals which constitutes the major error source estimated to be <10 Dobson units in a 95% confidence interval. This error can be further reduced by increasing the acquisition time.
- (2) The Rayleigh extinction by the atmospheric gas molecules: this uncertainty is reduced below 0.1 Dobson unit by correcting the lidar data using the pressure, temperature and humidity distribution as measured by radiosonde at the nearby meteorological station of Nîmes (44° N, 5° E).
- (3) The Mie differential extinction by aerosol particles: this uncertainty which can be large at lower altitudes² is reduced when using the A wavelength pair to measure the total content up to 15 km which leads to high ozone optical thickness as compared with the aerosol contribution. It can be estimated to be <1 Dobson unit whereas the use of the B pair in the same altitude range will have resulted in a one order of magnitude higher uncertainty.
- (4) A systematic bias due to the discrepancies already pointed out between the two wavelength pairs and the absolute cross-sections determinations.
- (5) A constant value of 10.4 Dobson units which corresponds to the average ozone content above 40 km (ref. 8): the 2σ -standard deviation results in a 3.2 Dobson units uncertainty similar to that introduced at the lower boundary by the extrapolation of the ozone distribution down to the ground level.

The lidar derived values of the ozone total content have been plotted on Fig. 2 together with the values obtained from the Dobson spectrometer measurements performed at Arosa (46° N, 10° E) and Biscarrosse. The values obtained on 29 and 30 November and 3 December are in a good agreement with a maximum difference of 3%. On 1 December a difference of 47 Dobson units is observed which decreases down to 25 Dobson units on 2 December. It corresponds to the variations measured between 10 and 18 km when considering the vertical distributions (Fig. 1) and can thus be related as already pointed out, to the horizontal transport. Further validation of the lidar system's ability to measure the total ozone content will imply correlative measurements with a Dobson spectrometer set up at the same location which is within the scope of future developments of the geophysical station at the Observatoire de Haute Provence.

The main advantage of the remote sensing technique described above is the direct determination of the ozone number density with an independent instrument which does not require any internal or inter-calibration. This advantage can then be extended to the measurement of the total ozone content. The preliminary measurements presented here will be improved: the development of new laser sources such as excimer lasers

providing higher output energy in the same wavelength range could thus be a further determining step.

This work was supported under contract 79-71020 from the Délégation Générale de la Recherche Scientifique et Technique. The development of the O.H.P. lidar facility is supported by CNRS and INAG. We thank Professor C. Fehrenbach, Director of the Observatoire de Haute Provence for hospitality, also Dr H. Dütsch and A. Lovisa for providing the results of the Dobson spectrometers and Brewer sonde measurements.

Copper sulphide $\text{Cu}_{1.8}\text{S}$ (Digenite I) precipitation in mild steel

J. E. Harbottle & S. B. Fisher

Central Electricity Generating Board, Berkeley Nuclear Laboratories, Berkeley, Gloucestershire GL13 9PB, UK

The microstructure of mild steel pressure vessel plate and weldments has recently been examined by transmission electron microscopy (TEM) to characterize certain numerous small ($<1,000 \text{ \AA}$) matrix precipitates and relate them to the bulk mechanical properties of the steel. The TEM examination was undertaken using in-line energy dispersive (EDAX) spectrometry. In view of the strong influence of Cu on radiation hardening and embrittlement in steels¹ particular emphasis was placed on the identification of any copper-bearing precipitates within the grains. We report here the first observation of discrete particles of copper sulphide, positively identified as $\text{Cu}_{1.8}\text{S}$ (Digenite I), and found only in the matrix of the mild steel weld specimens. In spite of having a similar copper content to the plate, the precipitation of copper sulphide uniquely in the welds is thought to arise from the high temperature oxidizing environment experienced during welding. This favours the formation of $\text{Cu}_{1.8}\text{S}$ in the presence of soluble copper from the less stable FeS commonly found in sulphur-bearing steels. The importance of this observation in relation to the mechanical properties of the steel is briefly discussed.

Examination of the microstructure of mild steel plate and weld materials, similar to those used for reactor pressure vessels, is aimed at identifying and measuring the matrix precipitate populations and relating their presence to the bulk mechanical properties. As the most numerous precipitates, and therefore those having the greatest hardening effect, are also the smallest ($<100\text{--}1,000 \text{ \AA}$) they require for identification micro-probe TEM with in-line EDAX and EELS spectrometers. These instruments permit concurrent convergent beam electron diffraction together with energy dispersive and energy-loss analyses. Electron microscope specimens in the form of extraction replicas of the steels were specially prepared and mounted to reveal precipitates having a wide compositional range. The composition typical of all the steels is: C 0.1, Mn 1.0-1.8, Si 0.1-0.4, Cr 0.05, Cu 0.05-0.2, S 0.01-0.03 wt %.

In view of the marked effect of small amounts of copper on certain post-irradiation mechanical properties^{2,3}, such as increases in yield stress and the ductile-brittle transition temperature, particular emphasis was placed on the detection and identification of copper-bearing precipitates in the grains. Special precautions were taken to eliminate stray copper signals from within the microscope. Before this study observations

Fig. 1 Bright-field micrograph of copper sulphide $\text{Cu}_{1.8}\text{S}$ precipitation in a mild steel weld grain.

have been reported on the presence⁴, but not the crystallographic identity, of small copper-bearing precipitates in the matrix of mild steels. Small unidentified precipitates have been seen on dislocations and in the grains following ageing^{5,6} and irradiation⁷ of Fe-Cu alloys. These were assumed to be either copper precipitates or copper-vacancy complexes.

In the present study, irregularly shaped precipitates having sizes in the range $100\text{--}360 \text{ \AA}$ and a density of $\sim 10^{11} \text{ mm}^{-3}$ were observed throughout the grains of the as-welded specimens. A typical bright-field micrograph is shown in Fig. 1. These precipitates were not present in the plate material. Energy dispersive analysis indicated the presence of only copper and sulphur (Fig. 2) and the associated electron diffraction patterns (Fig. 3) consistently fitted data from the f.c.c. copper sulphide phase $\text{Cu}_{1.8}\text{S}$ (Digenite I). Copper sulphide precipitation was also found after a typical stress-relieving anneal at 600°C for 6 h, demonstrating its stability at this temperature and indicating that it was formed at high temperature during the welding process. This result is the first experimental proof of the existence of copper sulphide in steels, the crystallographic structure having been originally determined from a sample of the naturally occurring digenite mineral⁸.

The possibility that copper sulphide may form in mild steels was first suggested by Melford⁹ in a study of surface hot shortness. A feature of this effect is the localized enrichment of certain residual elements (Cu, Ni, S, Sn) that occurs below the surface scale during heating in an oxidizing environment to temperatures in excess of $\sim 1,200^\circ\text{C}$. Similar conditions will prevail during welding. A microprobe analysis of a section through the scale showed⁹ that the copper peak often coincided with an enrichment of sulphur, suggesting the presence of copper sulphide. The close association of these two elements for an individual particle near the scale was verified by mapping, although no electron diffraction pattern was obtained to provide positive identification of the particular compound.

Due to its relative insolubility ($<0.03 \text{ wt \%}$ at $1,200^\circ\text{C}$) any sulphur present in iron during steel manufacture combines to form either MnS or FeS depending on the Mn:S ratio¹⁰. Copper on the other hand is soluble up to 9 wt % in γ -iron¹¹, varying little in the temperature range $1,050\text{--}1,250^\circ\text{C}$, and therefore remains free to combine with other elements during welding, for example. Free energy calculations⁹ show that, in the

Fig. 2 Electron diffraction pattern from the arrowed particle in Fig. 1. The zone axis is [001] and the camera constant = 23.61 mm Å.

presence of oxygen and at temperatures approaching melting, copper sulphide should form from either FeS or MnS, following the reactions

and

Although we have found MnS in the large weld product inclusions but not in the weld matrix, the presence of MnO is never detected. However, FeO is commonly found throughout the matrix. This suggests that reaction (2) is the most likely to account for the observed $\text{Cu}_{1.8}\text{S}$ and FeO in the weld metal, where the high temperature, oxidizing environment would favour the transformation of FeS and the formation of copper sulphide. These conditions are not met in general in the plate material and explains the absence of both copper sulphide and wüstite in these specimens.

This result contributes principally to the understanding of copper's role in changing the yield stress of irradiated or aged ferritic steels. Previously it has been assumed that the increased hardening (or DBTT) is due to all the copper, initially in solid solution, being free to form either copper-vacancy complexes during irradiation or precipitates during thermal ageing. This

Fig. 3 EDAX spectrum from $\text{Cu}_{1.8}\text{S}$ particle. The highest peak arises from the aluminium grid holding the replica.

result shows that a proportion (up to 100% in some welds) of the total copper is precipitated as $\text{Cu}_{1.8}\text{S}$ and is therefore no longer available as free copper atoms. This can significantly reduce its influence in causing subsequent increases in yield stress. Hawthorne's¹² recent measurements support these results by showing that the addition of sulphur always reduces the detrimental effect of copper on radiation sensitivity in steels. The net change in yield stress depends on the relative quantities of free and precipitated copper. By taking the latter into account a good correlation may be obtained between the yield stress increase of various irradiated steels and (soluble copper content)^{1/2} based on a barrier hardening model.

Pressure dependence of glass dissolution and nuclear waste disposal

R. A. Lewis & R. L. Segall

School of Science, Griffith University, Nathan 4111, Australia

Schemes to dispose of high-level radioactive waste by vitrification and subsequent burial call for an appraisal of the consequences of groundwater encountering the waste glass¹. Glass dissolution rates are influenced not only by properties of the glass and solvent themselves but also by properties of the combination such as the glass surface area to solvent volume ratio². Although pressure may affect glass dissolution rates, it has not received unambiguous explicit experimental investigation. A simple experiment has been designed to determine dissolution rates at room temperature of glass samples subject to very high pressure in a centrifuge. The results reported here show that the dissolution rates for Na and Si increase slightly with pressure, but that at a pressure of 160 MPa (>1,500 atm) these dissolution rates are still of the same order as those at atmospheric pressure.

Thermodynamic principles have been used to explain dissolution and redeposition under pressure in solutions at equilibrium³ but are not pertinent to dissolution kinetics which are dealt with here. Pressure effects on the solvent are not likely to be important in the dissolution double layer where large electric fields dominate⁴. Likewise, throughout this experiment, dissolution is not rapid enough for the diffusion of ions away from the surface to be a rate limiting factor. On the other hand, mass transport by diffusion in the glass might well be restricted by compression. Modification of the electronic surface states of the glass by pressure will alter their position relative to states in the solvent⁵. The application of pressure to elucidate electronic properties of semiconductors is well-known. Pressure may introduce a new, less stable phase in the glass or, in the extreme, devitrification. Hence, the study of the overall effect of pressure is germane to the development of a comprehensive theory of glass dissolution as well as having considerable practical relevance to high-level radioactive waste disposal.

Table 1 Glass composition (wt %)

SiO ₂	55.53
B ₂ O ₃	29.26
Li ₂ O	4.94
Na ₂ O	10.27
	100.00

The glass utilized was the precursor of a radioactive waste storage glass (designated 189 or M5) fabricated at AERE Harwell; its composition is given in Table 1. The stability of this simple glass in water is relatively poor. The complete high-level waste glass, which contains metallic oxides such as MgO and Al₂O₃ from Magnox waste, is considerably more durable. Beads of 2.5 mm diameter formed under surface tension by heating cubes of glass on graphite were used. The annealing sequence consisted of heating from 20 to 727 °C at 320 °C min⁻¹, holding at 727 °C for 2 min, cooling to 427 °C at 5 °C min⁻¹ and then to 20 °C at 80 °C min⁻¹. The surface is therefore well-annealed and, essentially, flame-polished. A bead was placed with 12.5 ml of deionized distilled water in each of three cellulose nitrate centrifuge tubes. The base of each tube was 152 mm from the centrifuge axis and the depth of water in each tube was 86 mm. These tubes, together with three tubes containing water alone, were spun at 20 °C in an ultracentrifuge for 45 h. The experiment was performed at centrifugation speeds 28, 35 and 40 × 10³ r.p.m. which correspond to pressures of 80, 120 and 160 MPa respectively. A control experiment consisting of six tubes was also left for 45 h without spinning. The liquid in each of the tubes was analysed for Na and Si in solution by flame atomic absorption spectrophotometry. The behaviour of the other glass constituents namely Li, an alkali and B, a glass former, would be expected to follow that of Na and Si respectively. The mean and the best estimate of the standard deviation, $\sigma(n/(n-1))^{1/2}$, for each set of data were calculated. The results for Na are presented in Fig. 1.

A small increase in the Na loss with pressure, is evident in Fig. 1. Using the Student's *t* statistic, the hypothesis that the amounts of Na measured in solution after attack at 0.1 and 160 MPa are the same is first rejected at a level of significance of 0.04. At the same level of significance the hypothesis can be rejected that the amount of Na in solution for the 160 MPa experiment compared with the one at 0.1 MPa is greater by a factor of two. It is plausible, therefore, to argue that Na leaching is slightly enhanced at the higher pressure. The analysis for Si in solution by flame atomic absorption is less accurate than that for Na, but Si exhibits a similar small increase in loss with pressure. Clearly no marked effect occurs.

Scanning electron micrographs of the glass beads before aqueous attack are basically featureless. After attack at both ambient and elevated pressures scanning electron micrographs show typical features of glass surfaces following aqueous treat-

Fig. 1 The effect of pressure on glass dissolution rates, measured by the ratio, *R*, of Na loss at pressure to ambient loss.

ment—fissuring and erosion. However, there is no systematic alteration in the surface features with increasing pressure.

A general theory of the progress of glass dissolution has yet to be developed, but three stages of aqueous attack may be distinguished. For short times, the loss of material from the glass is largely the product of alkali leaching and varies as $t^{1/2}$. This regime is conveniently described by diffusion theory⁵. During intermediate times, the amount of material in solution varies as t^1 , being the result of the constant break down of the glass network. Chemical kinetics are often used to explicate the pertinent mechanisms⁶. Over long times, when the glass is either completely dissolved or the saturation of the liquid ensures redeposition at the same rate as dissolution, the amount of material in solution is constant. This state is dealt with by thermodynamics⁷.

In the present case, considering the 0.1 MPa results, the extent of Na loss is $1.42 \pm 0.03\%$ and for Si the loss is $0.7 \pm 0.3\%$. Evidently the loss of Na by exchange with H⁺ has at least occurred, and may still be occurring, when the experiment was terminated. The comparable loss of Si indicates that network break down has also been taking place. The concentrations of these ions in solution—Na, $0.59 \pm 0.01 \mu\text{g ml}^{-1}$; Si, $0.9 \pm 0.4 \mu\text{g ml}^{-1}$ —is well below saturation. In relation to the three stages of attack outlined above, in the conditions of this experiment the glass has been subject to the first and the second, but not the third stage. This may appear surprising for aqueous attack at such a low temperature (20 °C) and for such a short duration (45 h). This glass, however, is known to be very easily corroded. Other experiments in our laboratory have shown that a 10 mm × 2 mm disk of the glass dissolves entirely in <48 h at 170 °C in 15 ml of water. A variety of nuclear waste glasses show only 0.5–2% dissolution when subject to these conditions.

A difficulty in interpreting glass dissolution measurements is the large number of variables which influence the glass-solvent interaction. These include properties of the glass, such as its composition, homogeneity, melt history, environmental history, surface preparation and physical form; properties of the solvent such as its pH and species in solution; and properties of the glass-solvent system, such as the duration of contact, nature of solvent flow and temperature⁸. While it cannot be asserted that the effect of pressure will be negligible in conditions different from those of the present experiment, a knowledge of the mechanisms of the attack contributes to confidence that this is so. No conspicuous difference in the amount of Na present as a result of ambient and high pressure attack is apparent. A difference would be expected if pressure grossly affected the mechanisms occurring at the $t^{1/2}$, or diffusion stage. Likewise, the lack of marked change in the Si concentrations indicates no large effect of pressure on the mechanisms operating at the t^1 , or network break down stage.

The maximum pressure considered in this experiment is more than seven times the pressure of water at the critical point (374 °C, 22 MPa) and well above that expected in underground high-level waste repositories⁹. This experiment provides no evidence that pressure effects will be of importance in the disposal of high-level waste in glass. Absence of a pronounced pressure effect on dissolution kinetics makes a useful simplification to the complex set of variables in the glass-solvent interaction.

Origin of sulphur and geothermometry of hydrothermal sulphides from the Galapagos Rift, 86° W

Polymetallic hydrothermal massive sulphides from a mid-ocean ridge were first recovered in 1978^{1,2}, from the East Pacific Rise (EPR) at 21° N, and later 'black smokers' were found³ debouching fluids at 380° ± 30 °C. The Galapagos Rift and Fracture Zone Intersection (GRAFZI) Project of 1980 discovered sulphides in inactive mounds with up to 27% Cu and 31% Fe at 86° W on the Galapagos Rift⁴, that are chemically very different from the EPR 21° N sulphides (up to 50% Zn). Stable isotope studies were initiated in an attempt to find the origin of the sulphide sulphur, to determine the temperature of formation of an equilibrium assemblage of chalcopyrite (CuFeS₂) and pyrite (FeS₂), and to understand the operative seawater/rock ratio, and therefore the controls on permeability of the oceanic crust responsible for producing hydrothermal sulphides. There has been relatively little similar work on samples from 21° N (refs 5–7). We report here results which indicate sulphide formation at 390° ± 20 °C that is almost identical to that of the 21° N black smokers which were measured directly by temperature probe. The seawater sulphate contribution to the sulphur of the sulphides was much more dominant than at 21° N (ref. 7), and suggests a more fractured crust and/or more rapid hydrothermal solution flow rates, induced from higher seawater/rock ratios.

Reflected light microscopy was used to select samples in which the finely intergrown pyrite and chalcopyrite appeared to have precipitated in isotopic equilibrium. The samples were subjected to quantitative X-ray diffraction⁸ to check their purity and the relative proportions of the two minerals of interest were determined to an accuracy of ±10%. Isotopic analyses of eight samples of sulphide and two of amorphous hydrated silica were carried out in late 1981.

The two samples of amorphous silica were subjected to a citrate/dithionite-buffered leach⁹ to remove contaminant iron oxides, and then heavy mineral separation to remove intermixed sulphides, before oxygen isotope analysis. After standard preparation of sulphur dioxide¹⁰ and oxygen (by fluorination¹¹), $\delta^{34}\text{S}$ and $\delta^{18}\text{O}$ results were produced using two separate VG Micromass mass spectrometers, a 602-C double collector and a 903 triple collector, respectively. Raw data were corrected for change-over valve leakage and for isobaric interference¹² and expressed relative to the Canon Diablo Meteorite, troilite phase (CDT) for sulphur, and standard mean ocean water (SMOW) for oxygen.

The inactive hydrothermal massive sulphides were recovered from the southern margin of the northern rift valley of the double-rifted system at 86° W, and were associated with a faulted perched block⁴ (Fig. 1). The hydrothermal vent system was located at a water depth of 2,850 m and extended for at least 1 km along the base of the fault scarp. The morphological and tectonic setting of this massive Fe–Cu sulphide bears many

similarities to the ophiolite sulphide deposits of the Troodos Complex^{4,13}. Chalcopyrite-rich samples were taken from a hydrothermal veinlet at the top of the inactive sulphide mound (Fig. 2). The samples rich in pyrite were taken from the mound middle, as were the amorphous silica samples. Paragenetic relations between chalcopyrite and pyrite indicate that they precipitated in equilibrium as was suggested by Styrer *et al.*⁷ for EPR 21° N sulphides.

Mineralogy exerts a control on $\delta^{34}\text{S}$ values and there is a linear relationship for samples 4, 6, 7 and 8 of high pyrite or chalcopyrite purity (Fig. 3). The isotopic data plotted against the chalcopyrite/pyrite composition (Fig. 3) show a spread of the eight data points with values for $\delta^{34}\text{S}$ between +5.42‰ and +6.34‰. The highest isotopic values came from pyrite-rich samples from the mound middle, while the lowest values were produced by mound-top chalcopyrite-rich samples. On extrapolation to pure end-member pyrite, (100% FeS₂) a value of +6.42‰ is obtained while 100% CuFeS₂ yields +5.38‰. The isotopic fractionation factor (α) of one sulphide species with respect to the other varies as a function of temperature. The calibration of Kajiura and Krouse¹⁴,

$$1,000 \ln \alpha_{\text{pyr}}^{\text{pyr}} = 4.5 (10^5 T^{-2})$$

yields a temperature of formation of 388° ± 20 °C for the GRAFZI pyrite/chalcopyrite mineral assemblage. The analytical precision averages 0.04‰, but values for individual samples have been indicated by error bars in Fig. 3.

The great spread of results, with four samples deviating from linearity (Fig. 3), may be explained in terms of the mechanism of transport of subsurface hydrothermally convected seawater. In a dynamic system of convectively circulated seawater, continuously interacting with igneous rocks at different temperatures at various seawater/rock ratios, in which H₂S and SO₄²⁻ are lost from solution by precipitation of sulphide and sulphate minerals, the budget of sulphur in the hydrothermal solutions must be changing constantly. Consequently, there are two possible explanations for the isotopic composition of the samples rich in pyrite (samples 1, 2 and 5 in Fig. 3) which fall below the best-fit straight line, and are therefore depleted of ³⁴S. Biological and diagenetic activity could reset and reduce the $\delta^{34}\text{S}$. The presence of organic debris was common in both GRAFZI sulphides (data not shown) and at the EPR 21° N (ref. 2). The second mechanism would involve augmenting the hydrothermal fluids with an increased amount of basaltic sulphur ($\delta^{34}\text{S} = +0.5$ to +1.0‰)¹⁵ as the fluids became progressively depleted in their seawater sulphate content ($\delta^{34}\text{S} = +20\%$)¹⁵, due to precipitation of sulphide and sulphate minerals within the upper crust.

The one isotopically heavy $\delta^{34}\text{S}$ value (sample 3) is problematical. This sample may have formed as a hydrothermal solution became isotopically heavier with time, possibly due to addition of more seawater sulphate from entrained seawater or due to operation of a simple closed reservoir where residual hydrothermal solutions became enriched in ³⁴S, as the ³²S isotope preferentially left solution on sulphide precipitation. The possibility of apparent ³⁴S-enrichment in GRAFZI samples due to the presence of micro-inclusions of isotopically heavy anhydrite can be ruled out as this mineral was not found, although Arnold and Sheppard⁵ noted anhydrite in EPR sulphides.

The two samples rich in amorphous silica gave the following $\delta^{18}\text{O}$ results: sample 9, +25.2 ± 0.8‰; sample 10, +17.0 ± 0.4‰. The large errors presumably are due to the presence of water in hydrated silica which may be retained to varying extents during analysis. These results imply formation at different temperatures or mixing of a high and low temperature amorphous silica product. It is interesting to calculate the range of temperatures from these values either in equilibrium with pure seawater (SMOW) or a heavier seawater representing exchange with hot basaltic material as at 21° N for example, +1.64‰ (ref. 16). The variability in published calibrations of this equilibrium fractionation^{17,18} produce further uncertainties in the temperature calculation. If all these variations are included,

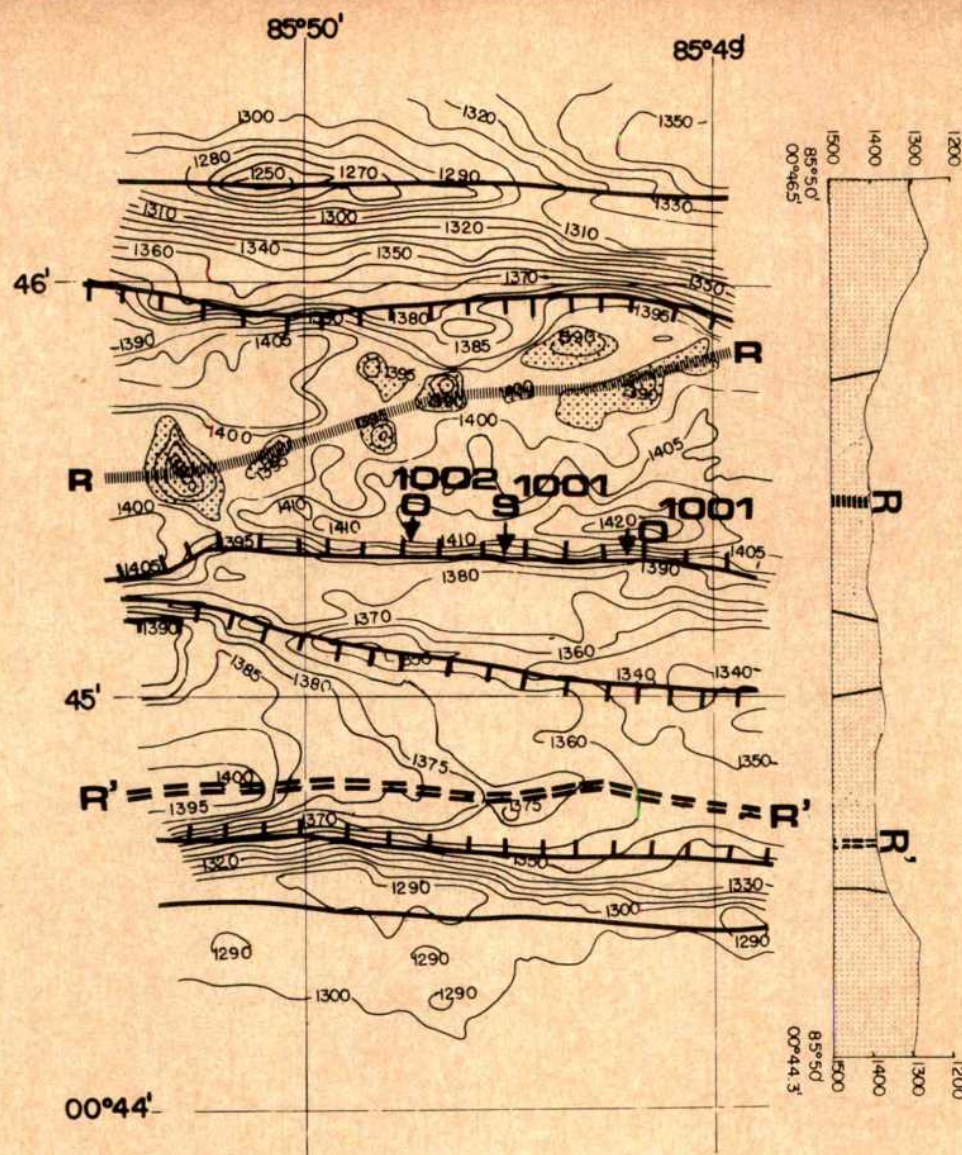

Fig. 1 High-resolution bathymetric map of the Galapagos Double Rift Area. R, principal rift axis; R', 'jumped' rift axis. The solid line delineates high crest on the tilted block and dotted areas indicate axial volcanic piles. Hashures indicate down-thrown side of normal faults; O, location of hydrothermal iron oxides; S, location of hydrothermal sulphide deposit mapped on dive 1001. (Depths in uncorrected fathoms.) After Malahoff *et al.*

the range of temperature for the two samples is from 60° to 172 °C. This suggests the possibility of considerable low temperature diagenetic additions of SiO₂ augmenting much lower temperature emissions than produced the sulphides, as has been noted for EPR 'white smokers'⁵. Amorphous silica probably formed at the periphery of the venting plume of hydrothermal water where mixing with ambient seawater occurred.

A comparison of $\delta^{34}\text{S}$ values between Recent and ancient submarine hydrothermal sulphides formed from modified seawater solutions¹⁹⁻²² reveals a similarity of composition (Fig. 4), although Kuroko deposits are associated with calc-alkaline volcanism rather than with deep-ocean tholeiitic basalts.

To compare Recent deposits in more detail, the hottest hydrothermal vents on the EPR at 21° N, at 380° ± 30 °C are actively debouching fluids which are precipitating mainly chalcopyrite, and these are very similar in temperature to GRAFZI inactive Cu-Fe sulphides which formed at 390° ± 20 °C. The overall chemistry of the two sulphide deposits is distinctively different, with the 21° N sulphides dominated by Zn, while GRAFZI deposits are richest in Cu and Fe. It is interesting to speculate whether the hottest 21° N hydrothermal vents,

Fig. 2 Hydrothermal veinlet from the mound-top rich in 'brecciated' chalcopyrite grains (up to 3 mm). The chilled margin of the veinlet with the rapid decrease in grain size and the gossan surface are particularly noteworthy features. Scale of veinlet, 18 mm long × 12 mm wide.

previously depositing Zn sulphide, but now Cu sulphide, are sealing themselves up, as GRAFZI sulphides once did.

$\delta^{34}\text{S}$ values for 21°N sulphides range from +1.3 to +4.1‰ and the sulphides received a 10% seawater sulphate sulphur contribution with 90% from basaltic leaching^{5,7}. Both experimental evidence²³ and now GRAFZI sulphide evidence have shown that the total hydrothermal $\delta^{34}\text{S}$ in a modern submarine deposit can exceed +5‰, and here ranges from +5.4 to +6.3‰. Styrer *et al.*⁷ observed that H_2S entirely of seawater origin may have $\delta^{34}\text{S}$ values as low as +5‰. If this is true, the entire sulphur of the GRAFZI sulphides may have a seawater sulphate origin. These sulphides are considerably enriched in ^{34}S compared with 21°N sulphides, suggesting a more dominant seawater source of sulphur at 86°W. This observation has profound implications, in that higher seawater/rock ratios than have been realised previously, can be responsible for the production of seabed hydrothermal sulphides. In terms of subsurface crustal structure, this would be manifested by a permeable, well-fractured oceanic crust and/or rapid flow rates for the hydrothermal solutions, which would allow great fluxes of seawater into the upper oceanic crust for convection and possible sea floor sulphide precipitation, on mixing with ambient bottom waters.

The analogy between GRAFZI and Cyprus-type sulphide ores can be carried further when considering stockwork hydrothermal fluid temperatures. These were found to range between 250°C and 350°C (ref. 24), and 300°C (ref. 25) by different workers on Cyprus-type sulphides of the Troodos ophiolite complex. Heaton and Sheppard²⁵ postulated a seawater/rock ratio of between 1 and 5 responsible for producing disseminated stockwork cupriferous pyrites with $\delta^{34}\text{S}$, +5.1‰ (Fig. 4), while massive pyrite gave $\delta^{34}\text{S}$, +4.3‰. These values are similar to GRAFZI pyrites (up to +6.3‰) but are generally slightly lower. Spooner²⁴ suggested a major component of sulphur for the sulphides from reduced seawater sulphate at Troodos, that is,

Fig. 3 $\delta^{34}\text{S}$ plotted against % chalcopyrite/pyrite mineralogy. Samples 1, 3, 4 and 8 from chalcopyrite-rich mound top. Samples 2, 5, 6 and 7 from pyrite-rich mound middle. The line is the best-fit straight line.

$$\Delta^{34}\text{S}_{\text{Pyr-Cpyr}} = \delta^{34}\text{S}_{\text{Pyr}} - \delta^{34}\text{S}_{\text{Cpyr}} = 6.42 - 5.38\text{‰} = 1.04\text{‰}$$

Fig. 4 Comparative sulphur isotopic data of some stratiform massive sulphide deposits associated with submarine volcanism, adapted from Ohmoto and Rye¹⁹. The sources of data on Cyprus and Kuroko are summarized in Rye and Ohmoto²⁰. The data on the Red Sea are from Kaplan *et al.*²¹, and Shanks and Bischoff²². EPR, 21°N, data are from Arnold *et al.*⁵ and Styrer *et al.*⁷.

10% and possibly up to 100%. Therefore, this seems to confirm our hypothesis of a major source of sulphur derived from seawater rather than basalt at 86°W, on the Galapagos Rift.

We thank NERC for provision of research funds and a research studentship to R.S.; Dr A. Malahoff of the National Ocean Survey; NOAA for donation of samples; Dr D. S. Cronan for invaluable discussions; Mrs M. A. Cox for analytical assistance; and Miss P. Raymond for preparation of the typescript.

Fluxes of biogenic components from sediment trap deployment in circumpolar waters of the Drake Passage

Gerold Wefer*, Erwin Suess†, Wolfgang Balzer‡, Gerd Liebezeit‡, Peter J. Müller*, C. André Ungerer† & Walter Zenk‡

* Geologisches Institut, Olshausenstrasse 40–60, 2300 Kiel, FRG

† School of Oceanography, Oregon State University, Corvallis, Oregon 97331, USA

‡ Institut für Meereskunde, Düsternbrooker Weg 20, 2300 Kiel, FRG

Circumpolar surface waters dominate the circulation of the Southern Ocean and sustain one of the ocean's largest standing stocks of biomass thereby producing a significant output of biogenic components, mainly diatoms, to the bottom sediments. Generally transit of biogenic matter from the sea surface to the sea floor affects nutrient regeneration fuels benthic life and transfers signals to the sediment record^{1–5}. Reliable quantification of the relationship between biological production, fractionation of skeletal and tissue components and bottom sediment accumulation depends on direct vertical flux measurements from sediment trap deployments^{6–9}, which have proved to be most scientifically productive^{10–13}. We now present data on vertical mass fluxes from the Southern Ocean and evidence for strong biogeochemical fractionation between organic carbon-, nitrogen- and phosphorus-containing compounds, siliceous and calcareous skeletal remains, and refractory aluminosilicates.

Results are from the first deployment of sediment traps in Antarctic waters. Our traps, with a collection area of 314 cm² (ref. 14), were attached to a moored array located at 60°54.6' S and 57°06.0' W in 3,625 m of water depth for 52 days from 2 December 1980 to 25 January 1981. During that time the integrated mean primary production in the study area was 0.1 g C m⁻² day⁻¹ (ref. 15). Current and temperature observations at 400 m, 1,500 m and 3,590 m of water depth revealed some unexpected results. The upper two current meters showed a general tendency of eastward water movement, although the short time series yielded no reasonable mean current vectors. The mean temperatures recorded were 1.76 °C and 1.20 °C at 400 m and 1,500 m, respectively. In both cases the standard deviation was 0.09 °C from 5,165 individual values.

In contrast to these mid-water current observations, which characterize the southern extension of the Antarctic Circumpolar Current in the Drake Passage, an unexpectedly persistent undercurrent was measured at abyssal depth. This movement feeds near-bottom water from the Scotia Sea continuously into the deep South Pacific Ocean, has a mean vector of 20.9 ± 5.3 cm s⁻¹ towards 222° relative to true north and maximum velocities of 32 cm s⁻¹ with an average temperature of -0.02 ± 0.06 °C. The countercurrent was also noted north of Livingston Island during the Dynamic Response and Kinematic Experiment (DRAKE) in 1979¹⁶.

Material in the sediment traps was recovered from water depths at 965 m and 2,540 m; the samples are designated M 269–965 and M 269–2540, respectively. Chloroform for preservation was released into the collecting vessel during trap deployment from an imploding glass vial. Surface particulate matter was also collected at the mooring site on 25 January 1981 for 8 h. About 3 m³ of sea-surface waters from the RV *Meteor*'s contamination-free pumping system were continuously filtered through a 75-µm mesh sieve to concentrate enough material for individual component analyses; this sample is designated M 8101–38.

On recovery the sediment trap material and the surface particulate matter were split into 10 aliquots by pipetting from a suspension in filtered seawater which was kept homogenous

Fig. 1 Relative changes in major phase composition of particulate matter with water depth in the Drake Passage.

by continuous agitation. To minimize bacterial degradation, splits were immediately poisoned with 100 p.p.m. HgCl₂ and frozen. Just before analysis, the samples were thawed and de-salted by repeated washings in distilled water, then they were freeze-dried. The wash water was retained for labile phosphorous determinations. The yields of 8 out of 10 splits gave total dry weights, estimated to be accurate to within 5 mg. These estimates were then used to calculate the total mass fluxes of 143 ± 1 g m⁻² yr⁻¹ at 2,540 m, 163 ± 2 g m⁻² yr⁻¹ at 965 m and 471 ± 6 g m⁻² yr⁻¹ at the surface. The measure for the mass flux at the surface is the product of the mean organic carbon fixation rate¹⁵ multiplied by the bulk mass of the surface particulate matter divided by the concentration of organic carbon, and is considered a first approximation of the net bulk production. All individual component fluxes will be calculated from these bulk flux estimates.

Individual splits were analysed for elemental and phase composition, amino acid, amino sugar and carbohydrate contents and foraminiferal counts, using methods described elsewhere¹⁷. In addition, hand-picked foraminifera were analysed for their stable isotope composition as described elsewhere¹⁸. Results of the major element and stable isotope compositions are listed in Table 1.

Most of the material collected in the traps, and virtually all of the surface particulate matter, was biogenic with a very minor portion of aluminosilicates. Figure 1 illustrates the relative changes in the major particulate phases with water depth. Whole individuals of diatoms, fragments and molds of crustaceans and tests of foraminifera were most abundant. The tests were almost exclusively of the left-coiling variety of the species *Globoquadrina pachyderma*. Faecal pellets were also common.

Quantitatively, diatomaceous debris is the dominant constituent as seen in the high SiO₂-content (Table 1, Fig. 1). Hereby the percentages listed refer to anhydrous SiO₂ only, thus the H₂O of diatomaceous opal, estimated to be between 6 and 9 wt%, may largely account for the unknown portion of the total biogenic matter.

The next most important phase is organic matter which shows a change from the surface particulates to the deep trap material in decreasing protein and labile phosphorus and increasing carbohydrate contents. Calcium carbonate and the aluminosilicate fractions increase in relative importance with water depth, obviously due to the more rapid disappearance of opal and

† C-org contents used in carbon budget of Table 2.

organic matter. This is evident when comparing the respective changes in component flux rates with water depth.

The total calcium carbonate flux (determined from Ca and CO₂ analyses) into the traps was 4.5 and 6.6 g m⁻² yr⁻¹, respectively; whereas the *G. pachyderma* test flux (determined from test counts) was $\sim 10 \times 10^5$ individuals for each trap. For the test sizes 125, 200 and 300 μm , individual weights ranged from 1.1 to 8.9 μg with a mean test weight of 5.2 μg , thus when comparing both fluxes, it appears that *G. pachyderma* may account for the entire calcium carbonate flux.

The stable isotope values of *G. pachyderma* for three size fractions are also listed in Table 1. The tests in both traps showed mean $\delta^{18}\text{O}$ values of 3.25‰ PDB and appear unchanged during growth. This is in contrast to results from other neritic environments where, in general, for the same species the larger (older) shells are enriched in ^{18}O (ref. 19). The constant $\delta^{18}\text{O}$ values may be due to the rather small temperature variation within the euphotic zone of the study area. Depth migration during growth, if it occurs in the life cycle of *G. pachyderma*, does not lead the organism to encounter large temperature changes in circumpolar waters. The mean $\delta^{18}\text{O}$ value of 3.25‰ PDB indicates an equilibrium precipitation temperature of +1.8 °C based on the 'calcite' palaeotemperature equation of Epstein²⁰ and assuming -0.65‰ for the circumpolar surface water²¹. The calculated temperature is in good agreement with measured ones which we have recorded; that is +3.0 °C at the sea surface, -0.26 °C at 100 m, +1.44 °C at 203 m and +2.01 °C at 446 m of water depth (R. Wittstock, personal communication). The salinity varies over this same depth range between

Organic phosphorus (insoluble), P-total minus P-hydrochloric acid soluble; calcium carbonate, mixed Ca-Mg-carbonate probably also containing SrCO₃; barite, soluble plus residual barium plus stoichiometric SO₄; aluminosilicates, sum of residual oxides plus 3 × (Al₂O₃) as aluminosilicate SiO₂; flux rates do not include quartz-SiO₂; the individual component fluxes are calculated by averaging the compositions.

33.7 and 33.5‰ S, therefore our data indicate that *G. pachyderma* precipitates its tests close to isotopic equilibrium. The carbon isotope values also do not vary with shell size and thus do not show the 'normal' trend of ¹³C enrichment with increasing age¹⁹, again the rather homogeneous water column properties seem responsible for this low variability in the stable carbon isotope signature of *G. pachyderma*.

Dramatic qualitative and quantitative changes with water depth were observed for the organic matter fraction (Table 2). Whereas in surface plankton 52% of the total organic carbon may be accounted for as being tied up in polypeptides, proteins and polysaccharides, these portions decrease with depth to 40% and 36%, respectively. The non-characterized fraction probably contains hydrocarbons, wax esters and other lipid material as well as 'humic matter'; its proportion increases with depth from ~50 to ~65% of the total organic carbon pool.

Because only < 1 μmol g⁻¹ of ammonia-N could be contained in the aluminosilicate fraction as fixed NH₃ (ref. 22), we assume that all nitrogen is organically bound. The free ammonia-N listed in Table 2 is also organically bound but is liberated from the protein fraction during hydrolysis.

The decrease in amino yield and the increase in carbohydrate contents with water depth reflect the preferential degradation of proteinaceous material²³. This is supported by a decrease in both amino acid-C and amino acid-N, whereas the relative increase in the non-characterized organic nitrogen fraction might reflect a pronounced abundance of nucleic acid bases and/or 'humic material'. Amino sugars on the other hand, comprise a relatively stable fraction of both organic-C and organic-N at all depths, indicating that they may be derived from poorly degradable chitinous matter.

For phosphorus we attempted partitioning by a methodology based on fractional solubilization. This approach explains why we account for the entire phosphorus budget. Hereby the water-soluble portion probably represents very labile organic phosphorus compounds such as ATP and related energy storage compounds and nucleic acids, released from living cells. We then defined a small fraction of phosphorus, soluble in hydro-

chloric acid, which could come from apatitic biogenous skeletons²⁴. Consequently, the calculated difference between P-sum minus P-HCl and P-leach represents an insoluble organic phosphorus fraction such as phospholipids from cell walls or similar tissue structures. The relative increase of this fraction from 10% at the sea surface to ~40% at depth also indicates it to be of a more refractory nature.

We may now compare flux rate changes of organic phases with mineral phases during transit through the water column (Table 3), because ultimately, fractionation resulting from such differential flux rates transforms surface particulate matter into bottom sediments. From Table 3, four types of biogeochemical regeneration can be differentiated. (1) Labile organic phosphorus is the most rapidly recycled; only < 5% of that fraction escapes recycling within near-surface waters and reaches depths of ~1,000 m, below which its flux remains essentially constant. (2) Polypeptides, presumably proteinaceous material of surface plankton are at first rapidly recycled between the surface and ~1,000 m of depth and thereafter at a slower rate. This exponential degradation is seen in changes of amino acid-C, amino acid-N and ammonia-N fluxes; it essentially affects the entire particulate nitrogen pool. (3) Fluxes of skeletal silica, polysaccharides, amino sugars and insoluble organic phosphorus show a slight tendency of refractory chemical behaviour which is marked by imperceptibly small flux rate changes in deep water. This is not surprising, as all are 'residual' components of biogenic matter: opal of diatom tests, carbohydrates and insoluble phosphorus of cell walls and amino sugars of chitinous skeletons. (4) Finally, the behaviour of calcium carbonate, barite and aluminosilicates cannot be adequately assessed from our flux data, because their sources are not restricted to surface waters of the same region as indicated by the deep countercurrent. Therefore, the bulk production rate assumed for the surface is a poor estimate. All three components of this group may have sources farther to the east of the sampling site and thus are not included in our production rate estimate from surface particulate matter. Similarly, aluminosilicates are advected horizontally and vertically throughout the water column, and the deeper the traps are deployed, the larger the aluminosilicate fluxes will be. But at least our flux data indicate that calcium carbonate, barite and aluminosilicates are very refractory and will undergo little, if any, recycling in the water column below ~1,000 m due to rapid transit.

This work was supported by the Deutsche Forschungsgemeinschaft and the US Office of Naval Research through grant N00014-79-C-0004, Project NR083-1026 to Oregon State University. We thank especially B. von Bodungen and R. Wittstock for help in deployment and recovery of the mooring in the Drake Passage. This is contribution no. 394 from the Sonderforschungsbereich 95, University of Kiel.

Extreme longevity of lotus seeds from Pulantien

David A. Priestley*† & Maarten A. Posthumus‡

In 1923 Ohga¹ first brought to general scientific attention the existence of a cache of viable seeds of East Indian lotus (*Nelumbo nucifera* Gaertn.), contained within an ancient lakebed deposit at Pulantien in southern Manchuria. From the geological and historical evidence available, Ohga suggested a possible age in excess of 400 years^{1,2}. Libby³ radiocarbon dated some of Ohga's material at 1040 ± 210 years BP. This evidence of great antiquity for viable seeds has been controversial⁴⁻⁶. The main hindrance to the resolution of the problem has been the paucity of available Pulantien seeds following the dissipation of Ohga's original collection⁷. Recently we have received four Pulantien seeds, three of which were viable, albeit lacking in vigour. The lipids of the unimbibed seeds were examined and found to be still highly polyunsaturated, suggesting that they had undergone little atmospheric autoxidation. Radiocarbon dating of one of the viable seeds suggested a probable age of about 466 years at the time of germination. This is the oldest viable seed for which an age has been directly determined.

The four seeds supplied to us (designated P1 to P4) were collected in 1952 at Pulantien (Hsinchin, Liaoning Province, People's Republic of China)⁸. Following collection they were stored under herbarium conditions. For comparative purposes, we have also analysed freshly grown lotus seeds (designated W1 to W3) obtained from a colony in Washington D.C. that had been derived from two Pulantien lotus seeds germinated in 1951⁵. Each of the Pulantien seeds had the morphological peculiarities described by Ohga⁹ as distinguishing them from recently grown lotus seeds—a waxless, dark-brown pericarp, slightly pitted and lacking a styler protuberance at the apical end. It should be noted that lotus 'seeds' are technically dry fruits, since the seeds in the strict sense are surrounded by an extremely hard pericarp. This massively thickened structure is highly impervious to water and gases unless it is radically scarified^{1,10}. In our investigations, the extreme basal tip of the pericarp was sawn off to expose a small cavity where the cotyledons had shrunk away from the inner pericarp wall. Approximately 10 mg of dry cotyledonous material was excised for lipid analysis and the remainder of the seed was subjected to a germination test. In all the seeds examined the cotyledons were white, except P3 which had dull yellow cotyledons. Germination was initiated by imbibing in tap water at 20 °C for 15 min. The seeds were then placed semi-submerged on cotton wool and left in darkened conditions at approximately 25 °C. All the seeds (except P3) showed some signs of germination within 72–96 hours. After 96 hours the 'fresh' Washington material had plumules extending 39–44 mm beyond the tip of the seed. The corresponding extensions for the Pulantien seeds were less than 20 mm for P1 and less than 10 mm for P2 and P4. During the same period P3 took up water, though the cotyledons did not maintain turgidity and its plumule showed no evidence of growth. After 96 hours, seeds P3 and P4 were heated in an oven at 110 °C for 2 days to kill and dry the material for radiocarbon dating. The seeds were dated at 340 ± 80 BP (GrN-11012) and 430 ± 100 BP (GrN-11013) respectively, which correspond historically (after calibration against dendrochronologically dated tree-rings¹¹) to AD 1440–1640 and AD 1410–1620. Seeds P1 and P2 were allowed to continue germinating and, after transplanting, they developed into

apparently normal plantlets possessing three or four leaves, at which stage observations were terminated.

One common hypothesis of seed ageing identifies the oxidation of polyunsaturated fatty acid as a possible primary lesion during dry long-term storage¹². Lipids from the lotus seeds were analysed, therefore, as important indicators of the extent of autoxidation in the tissue. The Washington seeds (W1, W2 and W3 of Table 1), which had all presumably matured under rather similar conditions, had very similar fatty acid contents. The degree of polyunsaturation was high, dienoic (C18:2) and trienoic (C18:3) fatty acids accounting for almost half of the total. The total lipid content of the seed was approximately 1% of dry weight. The Pulantien seeds had a more variable fatty acid content than their Washington counterparts, although their similarity to the latter is obvious (Table 1). The much lower linoleic acid (C18:2) content of P3 and P4 compared to P1 and P2 is unlikely to be due to oxidation during isolation. Linolenic acid (C18:3), which is much more sensitive to oxidative degradation, was still quite evident. Most likely, P3 and P4 matured in warm summers, whereas P1 and P2 developed under colder conditions favouring a higher degree of polyunsaturation. Such effects are known to occur in other species^{13,14}.

The oldest documented age for seed viability is for a lotus seed collected in China in 1705 which germinated in 1942, a lifespan of 237 years^{6,15}. Our own data for the Pulantien material suggests that an even greater longevity for this species is possible and that lotus seeds can maintain their high degree of polyunsaturation despite very long periods of quiescence. The situation in lotus is in contrast to that in maize (*Zea mays* L.), for example, which loses the bulk of its polyunsaturated fatty acid within about 100 years¹⁶. The two factors most in favour of prolonged longevity in the Pulantien seeds are probably the extremely thick pericarp and the generally reducing environment present in the peat within which they were deposited. It should be noted that enzymatic repair mechanisms are unlikely to operate in such seeds, which have a moisture content of approximately 11%¹. The lack of extensive lipid autoxidation in the Pulantien material probably accounts for the relatively well-preserved membrane profiles seen in ultrastructural studies^{17,18}. On the basis of such limited data it is difficult to speculate on the causes of viability loss in seed P3. Some lipid autoxidation may have occurred, but not enough to eliminate linolenic acid (C18:3) or to reduce the total level of polyunsaturation below that of the (viable) seed P4. The yellowing of the cotyledons of P3 is probably significant. In a previous study we noted similarly enhanced yellowing in corn seed that had lost viability during thirty to forty years of long-term storage, although this could not always be convincingly linked to fatty acid autoxidation¹⁹.

As noted by Godwin²⁰ complete credibility for claims of

Table 1 Fatty acid contents of Pulantien and Washington lotus seeds

	% Of total fatty acid						
	16:0	18:0	18:1	18:2	18:3	20:0	22:0
P1	25.0	1.3	11.7	49.2	4.5	2.5	5.7
P2	23.7	1.4	12.9	48.0	4.2	3.4	6.4
P3	34.7	2.4	11.8	39.5	2.6	2.5	6.5
P4	31.5	2.8	17.3	36.3	2.6	2.7	6.7
W1	21.6	2.1	19.6	42.4	5.1	3.5	5.6
W2	21.0	1.4	20.5	41.7	4.7	4.0	6.7
W3	22.7	1.3	20.4	43.0	4.6	3.5	4.4

Lipids were extracted from approximately 10 mg of cotyledonary material using 10 ml of chloroform:methanol (2:1, v/v). The solvent extract was filtered and washed once against 2 ml of 0.9% (w/v) NaCl. Fatty acid methyl esters were prepared according to ref. 24. Analyses were made using a Pye Series 204 gas chromatograph coupled to a VG Micromass 70–70 mass spectrometer system. The separations were on a 1.5 m × 2 mm column packed with 3% Silar 10-C on Chromosorb W-HP (100/120 mesh) using a temperature programme of 140–220 °C at 4 °C min⁻¹ or 120–220 °C at 6 °C min⁻¹. (16:0, palmitic; 18:0, stearic; 18:1, oleic; 18:2, linoleic; 18:3, linolenic; 20:0, arachidic; 22:0, behenic). Seeds P1–P4, Pulantien; W1–W3, Washington.

† Address for correspondence.

extreme seed longevity can come only from dating of the seed itself, preferably of a completely inert part such as the coat⁵. The mere dating of an object or structure associated with the seed is insufficient. With the possible exception of a reputedly 620-year-old *Canna compacta*²¹ seed, all other circumstantial claims for long lifespan are seriously suspect⁶. It is worth noting that not only are the lotus seeds among the oldest viable seeds recorded, but also their tissues must contain some of the longest-lived post-mitotic plant cells known. Although some trees such as *Sequoia sempervirens* and *Pinus longaeva* may attain ages of several millennia, the living cells in such structures are unlikely to exceed in lifespan a few decades at most^{22,23}. The cryptobiotic nature of well-protected dehydrated seeds such as the lotus assures their constituent tissues of a potentially much greater longevity.

We thank Dr Pei-sung Tang (Institute of Botany of the Chinese Academy of Sciences) and Dr Liu Shen-cheng (Beijing Botanical Garden) for providing seeds and Dr Horace V. Wester (National Parks Service, Washington DC) for donating freshly grown lotus seeds. Radiocarbon dating was carried out by Dr W. G. Mook (Laboratory of General Physics, State University of Groningen). We thank Professors Johan Bruinsma and Carl Leopold for encouragement. D.A.P. acknowledges the provision of a fellowship by the Netherlands Organization for the Advancement of Pure Research.

Leaf injury on wheat plants exposed in the field in winter to SO₂

C. K. Baker, M. H. Unsworth* & P. Greenwood

Department of Physiology and Environmental Science,
University of Nottingham School of Agriculture, Sutton Bonington,
Loughborough LE12 5RD, UK

The combined stresses of air pollution and low temperatures have been suspected as a cause of difficulty in establishing grasses¹ and trees² in upland areas of northern England. Davison and Bailey³ recently showed in controlled environment studies that exposure to SO₂ predisposed grasses to frost injury, and Keller⁴ has established that exposure to SO₂ of young spruce trees kept in cabinets outdoors over winter enhanced their sensitivity to frost injury the following spring. We report here the first observations of injury of winter wheat exposed in the field to controlled concentrations of SO₂ during the severe winter weather of December 1981 to January 1982. We conclude that the injury was probably caused by cold-stress after SO₂ exposure had rendered the plants cold-sensitive.

* Present address: Department of Botany, North Carolina State University, Raleigh, North Carolina 27650, USA.

A microcomputer-controlled system has been designed to release SO₂ from the upwind edge(s) of a square of pipes so that an area 20 m × 20 m in a normally-managed field of winter wheat can be exposed continuously to elevated concentrations of SO₂ from crop emergence in the autumn to harvest in the summer of the following year. The system, described fully elsewhere⁵, has been operated so that, independent of wind speed and direction, the SO₂ concentration at the centre of the square is maintained at a mean value of 100 p.p.b. (267 µg m⁻³ at 20 °C) above ambient, which is typically 10-20 p.p.b. at this site. Plants closer to the upwind edge are exposed to higher concentrations, typically 400 p.p.b. at 2 m from the gas release lines, whereas plants near the downwind edge experience lower concentrations, typically 20 p.p.b.⁵. Thus exposure in the treated area, other than close to the centre, depends on wind direction. By regarding the exposed area as a grid of 25 squares of 4 × 4 m and by combining measured SO₂ concentrations with a numerical diffusion model, the accumulated pollution dose in each grid square (concentration × time) is calculated by the computer.

The field was sown with winter wheat (*Triticum aestivum* L. cv. Bounty) on 23 September 1981. After emergence, the field exposure system was installed and release of SO₂ began on 27 November when the plants were ~4-5 cm high and had four leaves on the main stem. Exposure to SO₂ was continuous apart from breaks for system development and maintenance. Up to 11 December there were no significant differences between exposed plants and controls which were taken from an area ~60 m distant in which SO₂ concentrations did not differ from background values and where soil properties and microclimate were similar to those in the exposed area. On 11 and 14 December ~20 cm of snow fell, covering the plants completely. Gas release continued during the period of snow cover. On 23 December samples of snow (top few mm) were collected at the exposure and control sites for chemical analysis. The snow thawed on 31 December. During the period 12-30 December the mean daily maximum and minimum air temperatures at a Meteorological Office site ~400 m from the wheat field were 1.2 and -6.4 °C, respectively. After a brief mild period, very cold weather returned on 6 January and ~20 cm of snow fell on 8-9 January 1982, remaining until 16 January. Snow samples were collected on 12 January. In the period 6-15 January, mean daily maximum and minimum air temperatures were -1.7 and -9.2 °C, respectively.

A few days after the rapid thaw on 16 January it was clear that leaves of plants within the exposed zone had substantially more injured area than plants in the rest of the field. These injuries, which did not differ significantly throughout the 20 × 20 m zone, consisted of senescing tissue at the leaf tips; injured leaves appeared waterlogged and translucent. An independent assessment revealed no signs of disease. Table 1 shows the percentage of senescing tissue (lamina length) on leaves 4, 5 and 6 of exposed and control samples harvested on three different dates after the thaw. Data for leaf 3 are omitted because these leaves were senescing rapidly throughout the field at this period. Leaves 4 and 5 were injured significantly more in the exposed area; it seems that the injury on leaf 4 developed after the thaw, but injury on leaf 5 did not increase significantly after it was first recorded. A small amount of injury was observed on leaf 6 which emerged mainly after the thaw. Leaves emerging subsequently showed no injury.

We have examined three hypotheses to account for the injury observed:

(1) Leaves were injured due to 'acid' snow resulting from absorption of SO₂ at the snow surface. Injury would have been most likely when the snow thawed and plants were bathed in an acid solution.

(2) The injury was a response to SO₂ uptake by leaves after the plants had been made susceptible to SO₂ injury by low temperatures.

(3) Plants were injured by low temperatures after exposure to SO₂ had reduced their cold-hardiness.

The 'acid snow' hypothesis is not supported by our observations. Analyses of the two sets of snow samples showed insignificant differences between chemical composition of samples from the SO₂-exposed site and the control site. On 12 January the pH of the top few mm of snow ranged from 5.7 to 7.2 in the exposed area and from 6.4 to 7.6 in the control. Sulphate concentration in the snow was 9.5–14.4 µg ml⁻¹ and 9.3–10.8 µg ml⁻¹ at the exposed and control sites, respectively. Analyses of samples collected on 23 December also showed little difference between pH and sulphate concentration at the two sites. The lack of accumulation of sulphate in the snow at the exposed site is consistent with the low deposition velocity reported for SO₂ to snow⁶.

To investigate whether injury could have been caused to roots by a 'pulse' of acid or concentrated sulphate solution leached by melting snow from previously deposited sulphur on plants or soil, we analysed samples of soil solution collected by suction sampling from porous cups at 15 cm depth on 21 January. There were no significant differences in sulphate concentration in the soil solution between exposed and control areas.

It is more difficult to test retrospectively hypotheses (2) and (3). In support of the hypothesis that SO₂ uptake caused the injury is the observation that leaves harvested from near the centre of the exposed area on 21 January contained substantially more total sulphur than controls (8.4 ± 0.2 mg per g dry wt as opposed to 5.1 ± 0.1 mg per g). Dissolved SO₂ dissociates to phytotoxic sulphite and bisulphite forms⁷ and injury is more likely in cold conditions when oxidation to sulphate and other detoxification mechanisms are slow⁸. However, it is necessary to account for the uniformity of injury over the treated area where the dose experienced was very variable. Table 2 shows the computed SO₂ dose for each grid square during daylight hours in the period from 27 November until the injury was observed, excluding periods of snow cover. This dose, which varies by a factor of four across the exposed area would be expected to correlate well with absorbed SO₂ (ref. 9). Thus, unless there was a threshold sulphur content above which injury occurred independent of further sulphur uptake, or unless only leaf tips were susceptible to injury, it is impossible to explain the uniformity of injury. In addition, the symptoms of injury did not resemble the typical well-defined bleached areas attributed to SO₂ injury¹⁰.

The hypothesis that plants were injured by low temperatures after exposure to SO₂ had reduced their cold-hardiness, seems the most probable explanation for the injury, because at least two known mechanisms of SO₂ action on plants are likely to influence cold-hardiness in ways which could account for the uniformity of injury. Black and Black¹¹ observed that brief exposure of bean leaves to SO₂ concentrations similar to those in our experiment decreased the survival of cells on epidermal strips; survival rates did not depend strongly on concentration above ~80 p.p.b. If SO₂ exposure weakened membranes on wheat leaves, it seems likely that resistance to cold stress would be reduced. Alternatively, it is known that in plants where

Table 1 Injury on wheat plants harvested on three dates at a site exposed to SO₂ and a control site

Date	Site	Leaf no.		
		4	5	6
21/1	Control	12 ± 4	6 ± 3	0
	Exposed	16 ± 4	36 ± 5	0
3/2	Control	8 ± 2	10 ± 5	0
	Exposed	40 ± 5	44 ± 4	2 ± 1
12/2	Control	8 ± 2	6 ± 1	0
	Exposed	40 ± 2	40 ± 2	3 ± 1

Values shown are the mean percentage (±s.d.) leaf length injured for plants harvested on the dates shown from a site exposed to SO₂ and a control site. The first two harvests consisted of 6 plants from a larger sample of 0.25 m of two adjacent rows. The third harvest was 60 plants from each site.

Table 2 Cumulative SO₂ dose (p.p.m. h⁻¹) calculated for each 4 × 4 m grid square in the experimental area for the daylight hours of 27 November 1981 to 16 January 1982

51.3	28.5	25.8	26.9	40.4
49.0	20.0	16.0	17.2	31.2
49.5	20.1	16.0	16.9	30.3
51.0	24.1	21.3	21.0	31.7
68.7	54.1	51.1	49.7	52.2

Periods when plants were covered with snow are not included.

photosynthetic rates have been reduced or respiration increased, cold-hardiness may be reduced¹². Black and Unsworth¹³ demonstrated that SO₂ concentration > 50 p.p.b. reduced net photosynthesis in beans, and the reduction was independent of SO₂ concentration at low irradiance. Dark respiration was increased, also independent of SO₂ concentration.

We observed no injury after the first cold period even though the lowest night-time air temperature (–15.3 °C) was comparable with the lowest in the second period (–15.8 °C). Temperatures at the surface would have been even colder than these values. It may be that the intervening warm weather with maximum temperatures of 10–12 °C reduced cold-hardiness. On the other hand, day-time temperatures in January were much lower than in December, therefore a threshold for injury may have been exceeded, perhaps because repair mechanisms or replenishment of assimilates could not proceed at the lower temperature.

As with all post mortems, it is difficult to be conclusive about causes of injury. In particular the lack of replication of our treatment and control sites makes definitive interpretation of the causes of injury difficult. It seems essential, therefore, to test our hypotheses of the mechanisms of plant response by experiments in more controlled environments.

Whereas cereals are likely to recover from injury during winter, the delay in establishing leaf area could reduce yield if growth was limited later in the season, for example, by nutrition, drought or high temperatures. Frost injury enhanced by SO₂ exposure could not only reduce quality of horticultural crops but also, by delaying harvest, could cause large financial losses.

This work was supported by the Department of the Environment. We thank Sue Gregson and Geoff Dollard for chemical analyses and Colin and Valerie Black for helpful discussions.

Variation in genome size—an ecological interpretation

J. P. Grime & M. A. Mowforth

Unit of Comparative Plant Ecology (NERC), Department of Botany, The University, Sheffield S10 2TN, UK

Previous attempts to explore the significance of variation in genome size have involved comparisons with respect to life history^{1–4}, taxonomic and evolutionary affiliations^{5–9} and geographical distribution^{10,11}. Here we examine variation in the British flora. Large genomes are particularly associated with Mediterranean geophytes and grasses in which growth is confined to the cool conditions of winter and early spring. We suggest that large genomes have evolved under circumstances in which growth is limited by the effect of low temperature on rates of cell division and are part of a mechanism whereby growth at low temperature is achieved by rapid inflation of large cells formed during a preceding warm dry season. Where moisture supply allows growth to occur in the summer, temporal separation of mitosis and cell expansion confers no advantage and the longer mitotic cycle of large cells is likely to restrict rates of development; here the effect of natural selection has been to reduce cell and genome size.

Figure 1 describes the distribution with respect to genome size of various classes of flowering plants represented by 162 native or naturalized species of the British flora. Contrary to earlier observations^{1,11}, no consistent difference is apparent

between annuals and perennials. This is due to inclusion in the analysis of common perennial herbs, trees and shrubs, many of which (for example, *Epilobium hirsutum*, *Chamaenerion angustifolium*, *Salix caprea*, *Eriophorum vaginatum*) have comparatively small genomes. Grasses include many species with large (2C DNA >10 pg) genomes whereas low values are more typical of woody plants. Monocotyledons (mean 2C DNA = 17.28 pg) have significantly larger genomes ($P < 0.001$) than dicotyledons (mean 2C DNA = 6.86 pg). If comparison is restricted to herbaceous plants (Table 1) the difference in mean genome size between monocotyledons and dicotyledons is still observed but no consistent differences are associated with life history. When maps¹² are used to classify the species it is evident that plants found in southern Britain have markedly larger genomes. The mean genome size for the 69 southern species (mean 2C DNA = 13.31 pg) is significantly greater ($P < 0.05$) than that for the 80 species of widespread distribution (mean 2C DNA = 7.96 pg). Although data are available for only eight species, it is interesting that the mean value for plants of northern distribution is low (mean 2C DNA = 2.55 pg).

The species combining southern distribution and large genome size in Fig. 1 include a high proportion of geophytes and grasses with geographical ranges centred on the Mediterranean region. In most of these species, growth occurs during cool winter conditions and survival during the dry summer involves dormancy of both seeds and established plants. Similar phenologies are also common among the species of large genome size and widespread distribution in the British Isles. Here, however, the early development of species such as *Endymion non-scriptus*, *Ranunculus ficaria* and *Caltha palustris* occurs in relatively moist habitats and appears to provide a mechanism of evading competition from productive summer-green trees and herbs¹³.

The correlation between large genome size and the capacity for growth at low temperature is consistent with the enlarged genomes of cereals, grasses and legumes selected for superior

Fig. 1 Genome size in 162 flowering plants occurring in the British Isles.

a, Annuals; b, perennials (including biennials); c, grasses (stippled) and trees and shrubs (shaded); d, widespread distribution; e, southern distribution; f, northern distribution. The distribution for all 162 species is also reproduced in each subsection. In the following key to species and 2C DNA values (pg), original data (obtained by Feulgen microdensitometry on 10 nuclei from each of three seedlings) are distinguished by* from that collated by Bennett and Smith². *Achillea millefolium** (14.4), *Agrostis tenuis** (6.6), *Alliaria petiolata* (3.9), *Allium ursinum** (63.0), *Anthoxanthum odoratum** (11.8), *Anthyllus vulneraria** (1.0), *Aphanes arvensis* (1.1), *Arabidopsis thaliana* (0.5), *Arrhenatherum elatius** (16.0), *Artemisia absinthium* (7.3), *Arum maculatum* (21.8), *Avena fatua* (28.3), *Avena ludoviciana* (27.5), *Beta maritima* (2.6), *Betula pubescens** (1.4), *Brachypodium pinnatum** (2.3), *Brassica napus* (3.2), *Brassica nigra* (1.6), *Brassica oleracea* (1.8), *Briza media* (16.9), *Bromus commutatus* (21.7), *Bromus erectus** (22.6), *Bromus interruptus* (16.8), *Bromus lepidus* (15.7), *Bromus madritensis* (9.7), *Bromus pseudohominii* (19.7), *Bromus racemosus* (27.0), *Bromus rigidus* (17.2), *Bromus sterilis* (6.7), *Bryonia dioica* (3.3), *Caltha palustris* (33.0), *Campanula rotundifolia* (4.9), *Capsella bursa-pastoris* (1.4), *Cardamine flexuosa** (1.6), *Carex caryophyllaea** (1.5), *Chamaenerion angustifolium** (0.7), *Convallaria majalis* (49.3), *Crepis biennis* (16.9), *Crepis capillaris* (4.7), *Dactylis pilosa* (0.6), *Daucus carota* (2.5), *Digitalis purpurea** (2.3), *Drosera intermedia* (2.0), *Drosera rotundifolia* (1.8), *Endymion non-scriptus* (42.4), *Epilobium hirsutum** (0.6), *Eranthis hyemalis* (18.6), *Eriophorum angustifolium** (1.2), *E. vaginatum** (1.0), *Festuca ovina** (9.5), *Fritillaria meleagris* (141.4), *Fumaria muralis* (1.1), *Helianthemum chamaecistus** (4.5), *Helleborus niger* (22.8), *Holcus lanatus** (3.4), *Hordeum jubatum* (21.7), *Hordeum marinum* (11.0), *Hordeum murinum* (11.1), *Hordeum secalinum* (22.4), *Ilex aquifolium** (2.2), *Impatiens glandulifera** (2.2), *Lactuca serriola* (3.7), *Lamium album* (2.2), *Lamium purpureum* (2.2), *Lathyrus aphaca* (13.8), *Lathyrus maritimus* (15.6), *Lathyrus montanus* (16.5), *Lathyrus nissolia* (13.0), *Lathyrus sylvestris* (23.0), *Lathyrus tuberosus* (18.6), *Leontodon autumnalis* (2.7), *Leontodon hispidus** (5.2), *Lilium pyrenaicum* (65.5), *Lolium italicum* (9.8), *Lolium perenne* (9.9), *Lolium temulentum* (13.6), *Lotus corniculatus** (2.2), *Lotus tenuis* (1.0), *Lotus uliginosus** (1.1), *Lupinus arboreus* (1.6), *Luzula multiflora* (1.9), *Luzula sylvatica* (1.6), *Luzula sylvatica* (1.6), *Matricaria matricarioides* (4.6), *Matricaria recutita* (7.8), *Medicago lupulina** (1.6), *Melilotus alutissima** (2.5), *Mercurialis perennis* (4.7), *Mibora minima* (5.5), *Molinia caerulea** (4.6), *Montia perfoliata* (4.4), *Myosurus minimus* (2.2), *Origanum vulgare** (1.3), *Ornithogalum longibracteatum* (15.2), *Oxalis acetosella* (6.4), *Papaver dubium* (9.0), *Papaver rhoeas* (5.2), *Papaver somniferum* (7.6), *Petasites hybridus** (1.8), *Phalaris arundinacea* (11.4), *Phalaris canariensis* (7.7), *Pheum bertolonii* (3.4), *Picris echioides* (2.4), *Picris hieracioides* (3.1), *Pimpinella saxifraga** (9.5), *Plantago lanceolata** (2.3), *Poa annua** (3.8), *Poa infirma* (2.4), *Poa trivialis* (5.6), *Ranunculus acris* (10.7), *Ranunculus arvensis* (12.2), *Ranunculus auricomus* (18.0), *Ranunculus baud* (8.4), *Ranunculus bulbosus* (11.2), *Ranunculus ficaria* (18.6), *Ranunculus flammula* (12.7), *Ranunculus hederaceus* (4.2), *Ranunculus lingua* (50.2), *Ranunculus ophioGLOSSIFOLIUS* (11.3), *Ranunculus paludosus* (16.5), *Ranunculus parviflorus* (12.5), *Ranunculus repens* (22.4), *Ranunculus sardous* (6.4), *Ranunculus scleratus* (8.0), *Ranunculus trichophyllus* (9.7), *Ranunculus tripartitus* (9.0), *Rhinanthus minor* (7.9), *Rumex acetosa** (3.1), *Rumex obtusifolius** (2.7), *Salix caprea** (0.8), *Sambucus nigra** (2.9), *Sarothamnus scoparius** (1.7), *Senecio aquaticus* (3.6), *Senecio squalidus* (1.8), *Senecio vulgaris* (3.0), *Scirpus sylvaticus** (1.3), *Sieglingia decumbens** (5.9), *Silene dioica** (5.0), *Sonchus asper* (3.7), *Stellaria media* (2.1), *Taraxacum officinale* (2.6), *Thymus drucei** (2.6), *Trifolium arvense** (1.4), *Trifolium campestre** (0.9), *Trifolium medium** (6.7), *Trifolium pratense** (1.3), *Trifolium repens** (3.0), *Tripleurospermum maritimum* (5.3), *Tussilago farfara** (4.6), *Urtica dioica** (2.9), *Urtica urens* (0.6), *Veronica persica* (1.5), *Vicia bithynica* (9.1), *Vicia cracca** (11.4), *Vicia hirsuta** (7.2), *Vicia lathyroides* (5.2), *Vicia lutea* (14.8), *Vicia orobus* (10.7), *Vicia sativa* ssp. *angustifolia** (4.0), *Vicia sepium* (9.4), *Vicia sylvatica* (17.2), *Vicia tetrasperma* (7.4).

yield at high latitudes or elevations¹⁰ and with the low values reported for cacti² and tropical plants^{2,9,11}. It is at first surprising that the genomes measured in native plants of northern distribution in Britain (for example, *Eriophorum* spp., *Drosera rotundifolia*) are small. However, at high latitudes winter and spring are severe and unpredictable and the vegetation tends to be dominated by species in which both shoot growth and germination are delayed until the onset of warmer summer conditions^{14,15}.

The massive genomes reported for *Fritillaria* spp. ($2C$ DNA = 96.5–254.8 pg) and *Tulipa* spp. ($2C$ DNA = 39.9–90.6 pg)² are associated with the capacity for early and rapid expansion of relatively short-lived shoots and it is noticeable that their development precedes that of the spring grasses of more moderate genome size with which they are often associated in meadows and gardens respectively. Figure 2 provides a more objective test of the relationship between genome size and phenology. Measurements of the seasonal change in the shoot biomass of species established in natural herbaceous vegetation of the Sheffield region^{13,16,17} have been used to relate the timing of shoot growth in the spring to the genome sizes of individual species. Figure 2 includes all species for which quantitative measurements of both shoot phenology and genome size are available. The results indicate that from early spring to mid-summer changes in the identity of the most actively growing species are associated with a progressive reduction in genome size.

We suggest that the selective force determining this relationship between genome size and season of growth arises from a

Fig. 2 Relationship between genome size and time of shoot expansion in plant species commonly found in the Sheffield region (correlation coefficient significant at <0.001). The time of shoot expansion is calculated as the date to the nearest quarter-month at which 50% of the maximum shoot biomass was attained^{13,16,17}. Temperature in Sheffield is expressed as the long-term averages for each month of daily minima (□) and maxima (■) in air temperature 1.5 m above the ground surface. 1, *E. non-scriptus*; 2, *R. repens*; 3, *R. ficaria*; 4, *B. media*; 5, *A. elatius*; 6, *A. odoratum*; 7, *L. perenne*; 8, *F. ovina*; 9, *T. medium*; 10, *A. tenuis*; 11, *S. decumbens*; 12, *P. trivialis*; 13, *L. hispidus*; 14, *C. rotundifolia*; 15, *M. perennis*; 16, *M. caerulea*; 17, *P. annua*; 18, *H. lanatus*; 19, *U. dioica*; 20, *B. pinnatum*; 21, *L. corniculatus*; 22, *P. hybridus*; 23, *C. caryophylla*; 24, *C. angustifolium*.

differential effect of low temperature on cell division and cell expansion. As temperature rises during the spring the advantage of growth dominated by cell enlargement is likely to give way to that of growth involving high rates of cell division. Evidence supporting this hypothesis is available from studies¹⁸ in which mitosis has been shown to be inhibited at temperatures which permit high rates of cell expansion. Variation in genome size is implicated in this proposed mechanism by both our own unpublished observations which confirm that species which habitually grow by cell enlargement at low temperatures have relatively large cells and measurements^{19–23} establishing that potentially large cells have large nuclear volumes and high DNA contents. The mechanism dictating the strong correlation between cell size and nuclear volume remains obscure, although it has been suggested^{3,4} that large cells require an enlarged nuclear envelope to maintain adequate rates of nucleocytoplasmic transport of RNA. It is also possible that cells growing and functioning at low temperatures require more enzymes to sustain adequate metabolic rates. This may necessitate cell enlargement to accommodate extra protein, and higher DNA content could arise from 'dosage repetition'²⁴ of genes coding for proteins and ribosomes²⁵.

As the minimum duration of the mitotic and meiotic cycles is inescapably long in large cells^{19–23} the advantage of growth by cell enlargement would not be expected to pertain at warm temperatures. Thus, small genomes are observed^{2,26} not only in species of continuously warm tropical or arid environments but also in plants in which growth is restricted to the summer period in temperate, continental or arctic zones.

In the geophytes of very large genome size (such as *Fritillaria*, *Tulipa*, *Endymion*), growth occurs mainly by expansion of cells formed during warm relatively dry conditions of the preceding year²⁷. A similar, if less extreme, temporal separation of cell division and expansion may occur in grasses such as *Briza media* and *Anthoxanthum odoratum*, which in Fig. 2 follow the geophytes in the phenological sequence. Here spring growth involves the expansion of relatively large cells but it is less determinate and includes some cell division. In these species, we suggest that spring development may be sustained by the capacity for growth by cell expansion during intermittent cold periods and in the cooler parts of the daily temperature cycle. We suspect also that an integral part of this mechanism may be the accumulation of unexpanded cells during periods in which cell expansion but not cell division is restricted by moisture stress.

Patterns of variation in genome size may be useful in predicting plant response to climate, in crop breeding and in the analysis of niche-differentiation in plant communities. The data compiled by Britten and Davison²⁸ suggest that temperature may have played a major part in the determination of genome size in animals also. As might be expected, small genomes are characteristic of warm-blooded animals and it is particularly interesting that reptiles which flourish in dry hot conditions have uniformly small genomes whereas amphibians include species with exceptionally large genomes and cells. The respiratory system of amphibians depends on the maintenance of a moist permeable skin, so the ecology and behaviour of most species involve avoidance of insulation and maintenance of low body temperature. We suspect that particularly in amphibians exploiting temporary water bodies in a Mediterranean climate, there may be some temporal separation of cell division and expansion; in these conditions natural selection acting on rates of develop-

ment may have followed a course similar to that proposed for vernal plants.

Competition of similar and non-similar genotypes

J. M. Pérez-Tomé

Colegio Universitario Arcos de Jalón, Arcos de Jalón s/n, Madrid-32, Spain

M. A. Toro

Departamento de Genética Cuantitativa, Instituto Nacional de Investigaciones Agrarias, Carretera de la Coruña km 7, Madrid-35, Spain

It has been well established that the fitness of a genotype is often a function of the presence and relative frequencies of other genotypes coexisting with it^{1–3}. Facilitation or interference between individuals of like genotypes is suggested by some experiments^{4–9}, and it is commonly accepted that competition is an important element in agricultural practice^{10,11}. However, most such studies, at least those that use *Drosophila* as the experimental organism, involve strains which carry different mutations or chromosomal rearrangements. Here we demonstrate that competition of similar as opposed to non-similar genotypes can be detected in a random mating population not subject to genetic manipulation.

In the experiments reported here we used a population of *Drosophila melanogaster* founded from a cross of 70 isofemale lines derived from flies collected by E. Torroja in Carbonera (Almería) in September 1981. Since then the population has been maintained on Lewis food medium. The flies were kept in an incubator room at $25 \pm 1.5^\circ\text{C}$ under continuous illumination. All handling was at room temperature using ether anaesthesia.

Virgin males and females were collected within 6 h of emergence and placed in plastic or glass vials containing *Drosophila* medium, in groups of 20–30 of the same sex. The matings were set up when the flies were 3 days old by placing each one of 80 males with 10 females in a vial for 96 h, after which the male was removed. Two series of vials were then established. In the first, called the homogeneous series, the 10 females that had mated with the same male were placed in a 9×3 cm vial with 2 ml of medium. In the second, called the heterogeneous series, 10 females chosen randomly, but excluding any females

Fig. 1 Mean number of flies emerging daily for the homogeneous (□) and heterogeneous (▨) series.

mated with the same male, were placed in the same vial. All the females were transferred to fresh vials every 24 h for a total of four egg-laying periods. The progeny emerging in each vial were removed and counted daily until the cultures were exhausted.

The only difference between the homogeneous and the heterogeneous series is that in the first the full-sib families that compete are related as half-sibs whereas in the second these full-sib families are randomly assorted. However, the genotypes sampled in the two series are the same, thus explanations such as heterozygote advantage can be disregarded when interpreting the experiment.

Table 1 shows the mean productivity (number of flies emerging per vial) for the different egg-laying periods and the series. Figure 1 shows the daily mean productivity for the two series. This productivity is clearly greater in the heterogeneous than in the homogeneous series; and the difference between the total productivity of the flies in the two series is highly significant ($P < 0.005$).

The results presented here demonstrate clearly that in highly competitive conditions larval viabilities of *D. melanogaster* depend on the similarity of the genotypes coexisting. The productivity can be decreased by 17% merely by modifying the way in which the full-sib families compete.

There are two basically different mechanisms by which some larvae may affect the survival of others: (1) by diffusible metabolic products that affect the survival of other larvae; and (2) by differential utilization of niches by the different genotypes.

Table 1 Mean number of *Drosophila* emerging per vial for the different egg-laying periods and experimental series

Series	Period				Total
	1	2	3	4	
Heterogeneous	58.46 ± 3.16	53.62 ± 2.41	42.62 ± 1.93	37.49 ± 2.04	192.20 ± 5.3
Homogeneous	51.88 ± 3.41	39.88 ± 3.33	38.51 ± 3.00	32.86 ± 2.35	159.69 ± 9.90
t	1.43	3.38	1.16	1.49	2.94
P	<0.20	<0.001	<0.30	<0.20	<0.005

Approximately 35 vials were examined per period for each series; 10 flies per vial. Values shown are mean ± s.d.

It is not clear whether interference or facilitation is involved in these mechanisms.

These results have a bearing on the importance of frequency-dependent selection as an explanation for the maintenance of polymorphism, and are also relevant to the competition between genotypes important in agricultural practice. If this phenomenon is a general one it would also provide a mechanism for the maintenance of recombination through sib-competition¹². The simplicity of the experimental design presented here should allow us to explore more easily the nature of competition between genotypes.

Single cortical neurones have axon collaterals to ipsilateral and contralateral cortex in fetal and adult primates

Michael L. Schwartz & Patricia S. Goldman-Rakic

Section of Neuroanatomy, Yale University School of Medicine, New Haven, Connecticut 06510, USA

In the adult brain, cortical neurones that project to other cortical areas have traditionally been classified as either 'associational' (having connections within the ipsilateral hemisphere) or 'callosal' (projecting to areas in the contralateral hemisphere). Using double-labelling with fluorescent dyes^{1,2}, we have now identified a novel category of mature cortical neurone that has both an 'associational' and a 'callosal' axon. Such neurones can direct their callosal axons either to a cytoarchitectonic area homotopic to the one in which their cell bodies reside or to an entirely different heterotopic region in the contralateral hemisphere. These cortical neurones with divergent axon collaterals in the adult neocortex differ from recently described neurones that have two axons only transiently during development³⁻⁵.

Our evidence is based on data from two fetal (embryonic ages E132 and E137 respectively), two infant (4 and 12 days old respectively) and two adult rhesus monkeys. Each monkey received injections of one dye [Fast blue (FB), Nuclear yellow (NY) or propidium iodide (PI)] in the dorsal bank of the principal sulcus in the left hemisphere and injections of a second dye in the posterior bank of the intraparietal sulcus of the right hemisphere. In addition, one of the monkeys was injected with a third dye in the posterior cingulate cortex of the right hemisphere. Twenty to 72 h after the last injection, the animals were killed and their brains were immediately sectioned and prepared for microscopic examination. The distribution and morphology of labelled callosal neurones were determined in the principal sulcus, the intraparietal sulcus and the cingulate cortex (see outlined areas, Fig. 1). All three regions of association cortex receive projections from each other⁶⁻¹¹ as well as from the corresponding homotopic area in the opposite hemisphere^{6,7,12}.

Over 95% of fluorescent neurones in the areas examined were single-labelled with FB, NY or PI in all animals (Fig. 2a, b, e). Many of these were callosal neurones, retrogradely filled by dye injections in the corresponding cortical region of the opposite hemisphere. In agreement with previous studies^{10,13-15}, callosal neurones were concentrated in layer III, although some were also found in layers V and VI. All other single-labelled cells, also concentrated in layer III, were association neurones. For example, neurones in the principal sulcus were retrogradely filled by dye injections into the intraparietal cortex in the same hemisphere. Association and callosal neurones were generally intermixed rather than segregated into distinct laminar or radial groupings.

The remaining fluorescent neurones ($\leq 5\%$) were double-labelled and their percentage was no greater in fetuses or infants than in adults. This small population could be divided into two classes: (1) homotopic callosal neurones, which project one axon across the callosum to the same cytoarchitectonic cortex in the contralateral hemisphere (for example, left principal sulcus to the right principal sulcus) and a second axon to a distant cortical target in the same hemisphere (such as left principal sulcus to left intraparietal sulcus) (Fig. 2c, d); and (2) heterotopic callosal neurones which, like their homotopic counterparts, also have axon collaterals in both hemispheres. However, in this case, the target in the contralateral hemisphere is an area different from the homotopic site of origin. For example, double-labelled neurones were found in both anterior and posterior cingulate cortex in each hemisphere, indicating that a cingulate neurone can project simultaneously to the frontal cortex of one hemisphere and the parietal cortex of the other. In one animal injected with PI in the posterior cingulate cortex, several retrogradely labelled PI cells were found in the ipsilateral anterior cingulate cortex; some of them also contained FB which had been injected in the prefrontal cortex of the opposite hemisphere (Fig. 2e, f). Thus, these anterior cingulate neurones projected to both the posterior cingulate cortex of one hemisphere and the prefrontal cortex of the other.

Recent studies of cortical sensory areas in kittens³ and neonatal rats^{4,5} have suggested that, at early stages of postnatal

Fig. 1 The basic experimental procedure. Three monkeys received multiple 0.5- μ l injections of 5% FB in the posterior bank of the intraparietal sulcus (IPS) of the right hemisphere and multiple 0.5- μ l injections of 1% NY in the dorsal bank of the principal sulcus (PS) in the left hemisphere. One animal was injected with the same dyes but in reversed locations. The remaining two animals received injections of 3% PI and 5% FB, respectively, in the principal sulcus of the left hemisphere and 1% NY and 3% PI in the intraparietal sulcus, respectively, of the right hemisphere. Shaded areas represent injection sites; areas outlined by open rectangles indicate principle regions examined for cell labelling. Arrows indicate direction of projection of labelled neurones.

Fig. 2 Single- and double-labelled neurones photographed on a Leitz Orthoplan fluorescent microscope equipped with filter cubes D and M. With filter cube D both NY and FB can be simultaneously visualized in the nucleus and cytoplasm, respectively, of retrogradely labelled neurones¹. Filter cube M allows the visualization of PI in the cytoplasm of labelled cells². *a*, Layer III cell in the dorsal bank of the principal sulcus single-labelled with NY injected in contralateral principal sulcus (excitation wavelength 390 nm). Note that only the nucleus is labelled with this dye. *b*, Neurone single-labelled with FB following injection of FB in ipsilateral intraparietal sulcus. With this dye only the cytoplasm is labelled. *c*, *d*,

Double-labelled neurones in layer III from principal sulcus, where the nucleus shows intense yellow labelling with NY while the cytoplasm is labelled blue by FB. These neurones have both a callosal (contralateral) axon collateral to the homotopic principal sulcus and a divergent associational (ipsilateral) axon collateral to the intraparietal sulcus. Note that no significant NY labelling of glia was observed in the areas examined, indicating that, at the survival times used, the NY dye did not leech from labelled cells for re-uptake by nearby neurones and glial cells. *e*, Neurones situated in the anterior cingulate cortex labelled with PI following an injection in the posterior cingulate cortex of the same hemisphere (excitation wavelength 550 nm). *f*, The same field as in *e*, photographed at a different excitation wavelength (390 nm), showing that the neurone labelled PI-1 in *e* is labelled with both PI and FB. Thus, this double-labelled neurone projects to the contralateral principal sulcus and the ipsilateral posterior cingulate cortex.

development, a cortical neurone with intrahemispheric connections issues a callosal collateral which is later lost by selective elimination. In the present study, the density and distribution of double-labelled cortical neurones was the same in fetal, newborn and adult monkeys. It should be emphasized that our injections in monkey fetuses were made 1 month before birth at about the time that cortical axons penetrate the cortical plate in this species¹⁶. Thus, the difference between our findings and those previously reported in other animals cannot be easily attributed to differences in the stages of development examined. A more plausible explanation for the discrepancy between the present results and those of others³⁻⁵ is that there may be a genuine difference in the development of cortical connectivity in acallosal cortical areas such as primary visual cortex, on the one hand, and richly callosal regions of association and limbic cortex, on the other. In either case, our findings clearly demonstrate that for some cortical neurones, collateralization is not a transient developmental state but rather a permanent feature of their adult morphology.

The functional significance of the mature collateralized cortical neurones is not known. Obviously, the simultaneous influence of a single neurone on cytoarchitecturally distinct areas in the two hemispheres is an efficient means for coordinating the activity and transfer of information between widely divergent territories in the two halves of the brain. Such neurones could play a part in interhemispheric transfer by which information is made available to both hemispheres at once^{17,18}. In the present study less than 5% of all neurones were double-labelled, but the territories injected are only a fraction of the total callosal and intrahemispheric targets of the examined areas. Furthermore, although we did not find any triple-labelled neurones in the monkey with injections of three dyes, it is possible that some neurones have more than the two branches identified here. Indeed, future studies may reveal that the two classes of double-labelled neurones described here are actually

members of a single class of callosal neurone with multiple projections to both homotopic and heterotopic callosal targets plus one or more associational targets. Thus, the number of cortical neurones and the number of axon collaterals connecting regions within the same and opposite hemispheres may be considerably larger than indicated by the present results. Accordingly, these results provide new information for interpreting the functions, development and plasticity of the cerebral cortex and alter traditional views of cortical circuitry based on the existence of separate populations of associational and callosal neurones.

Similarity of unitary Ca^{2+} currents in three different species

A. M. Brown*, H. Camerer, D. L. Kunze* & H. D. Lux

Max-Planck-Institut für Psychiatrie, Kraepelinstrasse 2, D-8000 München 40, FRG

* University of Texas Medical Branch, Galveston, Texas 77550, USA

Membrane Ca^{2+} currents are the triggers for numerous cellular activities such as secretion, contraction, and oscillations in neural discharge. Different Ca^{2+} channels are assumed to subserve the various functions¹; this does not apply to Na^+ currents for which there is thought to be only one type of channel. We have examined single Ca^{2+} channels in cells from three very different species (bird, snail and rat) using the patch-clamp method², and report here that unitary events consisted of small, brief current pulses that often occurred in bursts and were similar for all three species. Thus, reported differences among various Ca^{2+} currents¹ must have other origins.

In our experiments, invertebrate neurones were represented by identified pacemaker cells³ of *Helix pomatia*, vertebrate neurones by cultured dorsal root ganglion (DRG) cells from chick (*Gallus gallus*)⁴, and vertebrate secretory cells by the PC12 line of cultured rat (*Rattus rattus*) adrenal medullary tumour cells^{5,6}. The cultured neurones have macroscopic Ca^{2+} currents that are similar to those of snail neurones^{3,4,7}. Snail neurones were isolated as described elsewhere³ and DRG cells

were prepared using a method that results in glia-free preparations⁸. At least 24 h elapsed before these cells were studied. PC12 cells grown according to Lucas *et al.*⁹ were studied 4–8 h after sub-culture. During experiments, cultured cells were viewed with phase-contrast optics through an inverted microscope. All experiments were done at 20–22 °C. Patch-clamp recordings were made using cell-attached patches and isolated patches in the inside-out configuration². The snail neurones were simultaneously voltage-clamped using a two-microelectrode method^{3,10}. Whole-cell clamping with the patch pipette was done in some DRG and PC12 cells.

Single channel Ca^{2+} currents were separated using solutions which suppressed Na^+ and K^+ currents. Osmotic strengths were 250 and 320 mosM for snail and vertebrate cells, respectively. In bath and patch pipettes, Na^+ and K^+ ions were replaced with (mM): Tris 60–100 or Cs 60–100, and tetraethylammonium (TEA) 10–60. The anions were Cl^- and/or gluconate. Tetrodotoxin (TTX), 2–5 μM and 4-aminopyridine (4-AP), 5 mM were added in most experiments. Ca^{2+} was present in concentrations of 20 or 40 mM in the patch pipette, except in some experiments where 20 mM BaCl_2 replaced CaCl_2 ; pH was buffered to 7.4 by Tris or HEPES (Serva). For inside-out patches the bath solutions contained (mM): Cs gluconate (60–80 for snail; 130 for vertebrate cells), hemi-Mg gluconate 20–40, EGTA (Titrplex VI; Merck) 1.0, and TEA-Cl 10–20; pH was buffered to 7.2 using Tris. Similar 'intracellular' solutions were used in the patch pipettes when whole-cell recordings from vertebrate cells were made. In the case of snail neurones, TEA was electrophoresed³ to produce estimated intracellular concentrations of 20–50 mM.

Voltage and current data were recorded on analog tape. Currents were low pass-filtered at 1 or 2.5 kHz by a 4-pole active filter and were digitized at 0.15–0.25 ms per point using a PDP 11/34 minicomputer. Control and test records were

Fig. 1 Unitary membrane Ca^{2+} currents from a snail neurone. The entire neurone was voltage-clamped. Top traces show the patch Ca^{2+} currents and bottom traces the whole-cell membrane Ca^{2+} current during steps to indicated membrane potentials from a holding potential of -50 mV. Linear components of leakage and capacitance have been subtracted. Ca^{2+} concentrations in the patch pipette and bath solution were identical (40 mM). Average unit current amplitude is indicated by dotted lines, and baseline values by the solid lines. As the potential was increased, the frequency of channel openings increased, simultaneous openings from 2 units appeared and unit amplitudes decreased. The data were filtered at 1 kHz.

Fig. 2 *a*, Unitary Ba^{2+} currents from a DRG cell-attached patch at different potentials. The dotted line indicates the time of the voltage step. Components of leakage and capacitance have been subtracted. A resting membrane potential of -50 mV was assumed. The threshold for activation of unitary Ba^{2+} currents was -20 mV. With increasing potential, the frequency of channel openings increased. Openings that occur in a burst were observed. Sections of the current records marked with an arrow in the left-hand panel are shown on an expanded time scale and bandwidth in the right-hand panel; the data were filtered at 1 kHz and 2.5 kHz, respectively. *b*, Unitary Ba^{2+} currents from a PC12 inside-out patch at $+30$ mV. Note a burst of openings with a superimposed single opening. Holding potential, -50 mV. *c*, Unitary Ca^{2+} currents from a DRG inside-out patch at $+20$ mV. Holding potential, -50 mV. Data were filtered at 1 kHz (*b*, *c*). 20 mM Ba^{2+} (*a*, *b*) or Ca^{2+} (*c*) was present in the patch pipette.

0.3–1.0 s long, and sets of at least 12 records were used for unit analysis.

Background noise was 0.1–0.2 pA r.m.s. at d.c. to 1.0 kHz bandwidth. As the signal-to-noise ratio was low, we used two different methods of measuring amplitudes and open and closed times. With the first method an interactive program was used to excise unitary currents that occurred singly or in bursts. Mean values for the background current were computed and used as reference levels. This method required subjective estimates of the unitary currents. A more objective method was to apply threshold levels at $\sim 2/3$ and $1/3$ of the expected current amplitude to mark the beginning and end of a channel current. When necessary, time-varying mean currents were removed before computing the histograms. The different methods were applied to two sets of identical data and were found to give similar results.

In snail neurones, the membrane potential was recorded directly together with macroscopic currents. Unitary patch currents which appeared similar were recorded repeatedly from different parts of the same neurone) this apparently caused no

damage to the cell, although an inward current often appeared transiently on removal of the patch electrode. Membrane potential was not recorded in DRG and PC12 cells. However, the resting potentials^{6,11} were probably similar to the holding potential of -50 mV used for snail neurones.

Unitary currents were observed following $G\Omega$ seals in 13 patches from DRG cells, 16 patches from PC12 cells, and > 200 patches from snail neurones. In all cases, these currents were characterized by the appearance of brief current pulses of small amplitude (0.5 ± 0.1 pA) at potentials that were depolarized by 20–30 mV from the resting potential. The openings occurred throughout steps of 1.0 s duration, but appeared to be less frequent at longer times. The openings occurred singly or in bursts (see Figs 1, 2). Long openings without evidence of any closure were also observed. Occasionally, amplitudes of about twice the unit height (Figs 1, 2b) were observed; these were interpreted as simultaneous openings of two channels. Openings became more frequent with increased depolarization (Figs 1, 2a), and the unitary current amplitudes decreased. In snail neurones the slope conductance was calculated to be 6–7 pS.

Table 1 Ca^{2+} channel characteristics

	Snail neurone	Rat PC12 cell	Chick DRG neurone
Current amplitude \pm s.d. (pA)	-0.47 ± 0.11 (120)	-0.53 ± 0.12 (1115)	-0.53 ± 0.10 (790)
Closed time (ms)			
within bursts	1.3 (15)	0.9 (543)	0.7 (274)
between bursts	46.2 (94)	21.9 (550)	20.7 (484)
Open time (ms)	2.8 (120)	2.7 (1115)	0.5 (790)
Duration of bursts (ms)	3.4 (106)	6.8 (577)	1.5 (516)
No. of openings per burst	1.2 (106)	1.9 (577)	1.5 (516)
k_2 (ms^{-1})	0.64	0.58	0.95
k_3 (ms^{-1})	0.13	0.53	0.48
k_4 (ms^{-1})	0.36	0.37	2.00

Mean values of Ca^{2+} channel characteristics from cell-attached patches of snail neurone (-20 mV), rat PC12 cell (-10 mV) and chick DRG neurone (10 mV). For analysis, we selected recordings which showed a discrete amplitude level on opening, presumably from one channel, and came from 1, 3 and 2 cell-attached patches for snail, rat and chick cells, respectively. The resting potential of DRG and PC12 cells was assumed to be -50 mV; that of snail neurone was -50 mV. Patch pipettes contained 40 mM Ca^{2+} for snail neurone and 20 mM Ba^{2+} for PC12 and DRG cells. The standard deviation of current amplitudes was due almost completely to the background noise current. In the calculation of the duration of bursts and number of openings per burst, single openings have been included. k_2 , k_3 and k_4 are the rate constants estimated according to the three-state model¹⁸. Numbers in parentheses represent the numbers of measurements from which the values shown were calculated. In the case of the closed times, the numbers were estimated from the integrals of the fast and slow components. The amplitude and open time values for the snail neurone patch are similar to values from larger samples, recorded previously¹⁰.

Fig. 3 Histograms of amplitude (a), open time (b), closed time (c, d) and burst duration (e) distributions for unitary Ba^{2+} currents from a PC12 cell-attached patch. Ba^{2+} concentration was 20 mM. The closed time distribution is shown on two different time scales to allow the two exponential components to be distinguished easily. Holding potential was assumed to be -50 mV and the patch potential was stepped to -10 mV. The histograms were computed from 21 records, each of 500 ms duration. Data were filtered at 1 kHz and sampled at 4 kHz. Values were obtained by the threshold method described in the text. The exponential curves in the histograms have time constants of b, 1.3; c, 1.8; d, 17.0; and e, 1.9 ms.

The inward currents became slightly larger when Ba^{2+} replaced Ca^{2+} (Fig. 2a, b). For inside-out patches the pipette interior was made positive by 50–70 mV. In the case of cell-attached patches, channels were activated with depolarizing steps ranging from 30 to 100 mV, and openings became more frequent at larger depolarizations. The currents remained almost unchanged for 10–15 min, which was the usual survival time of the inside-out patches in our solutions.

Table 1 gives the similarities in average amplitudes of the unitary currents for the different cells from the three species examined. Open times for snail neurones and PC12 cells showed similar distributions; the values for DRG cells were shorter, possibly because of differences in resting and activating potentials. The properties of the bursts were similar (see Fig. 3). The open times were described by a single exponential function. The closed times were similar among the different cell groups and could be separated into two exponential functions having short and long time constants. The short time constants are due to the intervals associated with bursts of activity, which were more prominent for Ba^{2+} currents. The longer time constants are due to the intervals between bursts.

The unitary activity could not have been produced by the flow of Ba^{2+} or Ca^{2+} through Na^+ or K^+ channels as the former

were blocked by TTX and the latter by TEA, 4-AP and Cs substitution. TTX-resistant Na^+ channels can be excluded as they do not conduct Ca^{2+} ions¹². The present inward currents were never observed when 10 mM Mg^{2+} or Co^{2+} replaced Ba^{2+} or Ca^{2+} , consistent with observations on macroscopic Ca^{2+} currents. The unitary Ba^{2+} currents were rather larger, a result also predicted from the macroscopic currents⁷. The unitary current amplitudes agree with those reported previously¹⁰ but are larger than values estimated from noise measurements^{13,14}. The present data are insufficient to allow any significant conclusion to be made regarding differences between divalent cations or the effects of changes in divalent concentration.

Our data do, however, indicate that open Ca^{2+} channels have only one conduction level. The bursting activity points to the fact that activation is more complicated than a simple first-order process; see also ref. 10. Further evidence for this is the delayed turn-on of Ca^{2+} currents which can be fitted by an m^2 model¹⁵ and the bi-exponential nature of Ca^{2+} tail currents^{16,17}. The simplest kinetic scheme consistent with our data is

where A and B are closed states and O is open. The rate constants k_2 , k_3 and k_4 can be estimated from the histograms¹⁸ and are given in Table 1. This model was also used by Fenwick *et al.*¹⁷.

The units of Ca^{2+} conduction were similar in the three different species studied here. The unitary currents produced in isotonic Ba^{2+} solutions in bovine chromaffin cells¹⁷ and in neonatal rat heart cells¹⁹ also resemble the units described here. It is possible that, as the cells from two of the species were cultured, the units might not be representative of the original cells. This possibility cannot be excluded, but the fact that the Ca^{2+} currents and action potentials recorded from these cultured cells^{4,11} are very similar to those recorded from a wide range of species and tissues renders such a suggestion unlikely. Hence, we conclude that Ca^{2+} channels everywhere are basically the same. The reported differences among macroscopic Ca^{2+} currents may be due to, among other factors, the variety of receptors associated with Ca^{2+} channels^{4,20} and the second-messenger actions of Ca^{2+} ions²¹.

We thank Drs C. Lucas, Y. Barde and R. Deisz, Ms G. Schuster and Ms S. Messerschmidt, and Mr R. Childers. We especially thank Mr H. Zucker for help with the computer programs and Drs E. M. Fenwick, A. Marty and E. Neher for providing us with a preprint of their paper. A.M.B. was supported by a Josiah Macy Fellowship and NIH grant NS 11453. H.C. was supported by DFG grant HE 1120/2-2.

Single-channel currents in isolated patches of plasma membrane from basal surface of pancreatic acini

Y. Maruyama & O. H. Petersen*

The Physiological Laboratory, University of Liverpool, PO Box 147, Brownlow Hill, Liverpool L69 3BX, UK

Precise localization and characterization of conductance pathways in glandular epithelia have so far proved difficult¹. The patch-clamp technique for high resolution current recording²⁻⁴, which has already been applied successfully to a number of electrically excitable cells^{3,4}, can in principle overcome these difficulties. We now report measurements of single-channel currents from isolated patches of plasma membrane (inside-out) from the baso-lateral surface of collagenase-isolated rat and mouse pancreatic acini. We have identified a cation channel having a conductance of ~ 30 pS and a mean open time in the range 0.3–1 s which is dependent on internal calcium. The single-channel current–voltage relationship is linear and the mean open time independent of the membrane potential. These channels may, at least in part, account for the Ca^{2+} -mediated neural and hormonal control of pancreatic acinar membrane conductance, which is probably responsible for the Ca^{2+} -dependent acinar fluid secretion⁵⁻⁷.

We used collagenase-isolated rat or mouse pancreatic acini prepared as described previously⁸⁻¹⁰. With this procedure, clusters of acinar cells (5–20) retaining intact tight junctions and the normal morphological polarity are obtained⁸⁻¹⁰. Fabrication of patch recording pipettes, isolation of inside-out membrane patches and high-resolution current recording were carried out as described in detail by Neher and collaborators^{3,4,11}. The total Ca^{2+} concentration in the bath and pipette solutions used was measured by atomic absorption spectroscopy.

Figure 1a shows current recordings from a single patch of plasma membrane with Na-sulphate solution on both sides of the membrane. We observed unitary events of constant amplitude at the same numerical membrane potential (–20 and +20 mV), but with a larger amplitude at a higher membrane potential (–40 mV). In the absence of a membrane potential, no unitary steps were detected. Unit current steps of this type were observed in 47 patches from 28 batches of isolated rat pancreatic acini. Similar experiments performed on pancreatic acini from mice revealed the same type of unit current steps (8 membrane patches from 4 batches of acini).

There was a linear relationship between the amplitude of the unitary current steps and the membrane potential, with reversal of current polarity at 0 mV. At zero membrane potential we observed no channel opening or closure using the same NaCl or Na_2SO_4 solutions on both sides. The existence of a Ca^{2+} gradient, typically 1.28 mM in the pipette and 40 μM in the bath, did not change the reversal potential. Figure 1b shows plots of single-channel current–voltage relationships from one series of experiments in which NaCl or Na_2SO_4 solutions (same concentration on both sides of the membrane) were used. As the single-channel conductance was independent of the presence of Cl^- , these channels seem to be cation-selective. Figure 1b also includes data from experiments in which $\sim 50\%$ of the Na_2SO_4 was replaced by K_2SO_4 , this did not change the conductance. It seems reasonable therefore to assume that the channels do not discriminate very well between Na^+ and K^+ . The mean value of the single-channel conductance in the three experiments carried out in NaCl solutions was 27 pS, whereas in one series with Na_2SO_4 solutions a mean of 33 pS (10 patches) was obtained.

Fig 1 Single-channel current–voltage relationship. *a*, Recordings of single ion channel currents from isolated membrane patch taken from the baso-lateral surface of collagenase-isolated rat pancreatic acinus. Short segments of the recordings from the same patch at four different membrane potentials are shown. The isolated membrane patch was 'inside-out', that is, the physiological inside of the membrane faced the bath, whereas the outer surface of the membrane faced the interior of the pipette. Outward currents (current from the intracellular to the extracellular side of the membrane) are represented by upward deflections. The membrane potentials indicated are conventional in that, for example, a potential of –40 mV denotes that the physiological inside of the membrane is 40 mV negative with respect to the outside. The patch resistance was 5 G Ω . In this experiment the same solution was present on both sides of the membrane and had the following composition (mM): Na_2SO_4 , 80, KCl, 4.7, CaCl_2 , 1.28, MgCl_2 , 1.15, glucose, 10, HEPES, 10. The pH of the solution (titrated by NaOH) was 7.3 and the temperature 22 °C. 20 Hz filtering (low pass) was applied. *b*, Relationship between the single-channel current and membrane potential. Values shown are from experiments in which (●) a solution with 110 mM NaCl, 10 mM HEPES, 10 mM glucose, 1.15 mM MgCl_2 and 4.7 mM KCl was present on both sides of the membrane; (□) a Na_2SO_4 solution (NaCl replaced isosmotically by Na_2SO_4) was present on both sides; and (■), a solution with 40 mM Na_2SO_4 and 45 mM K_2SO_4 was used on both sides. In these three series of experiments the external total Ca^{2+} concentration (pipette fluid) was in the range 1.28–2.56 mM, while the internal total Ca^{2+} concentration (bath fluid) ranged from 40 μM to 1.28 mM.

* To whom correspondence should be addressed

Fig. 2 Temporal characteristics of channel opening and closure *a*, Continuous trace of single-channel current recording from an inside-out patch exposed to Na-sulphate solution on both sides with 2.56 mM Ca^{2+} in the pipette fluid and 40 μM Ca^{2+} in the bath fluid. The Mg concentration on both sides was 1.15 mM, membrane potential, -50 mV, patch resistance, 15 G Ω . The frequency distributions of both the open and closed times for all the events in the entire recording ($n = 94$ and 77, respectively) were similar to exponential distributions with a single-channel mean open time of 0.93 s and a mean closed time of 0.83 s, if we assume that there are three mutually independent channels and that opening and closure of each of these is a Poisson-type phenomenon. Clamping the membrane potential at 0 mV abolished unitary current steps in this and all other experiments. *b*, Histograms obtained from one membrane patch at membrane potentials of -40 mV (\bullet , $n = 108$) and +40 mV (\blacktriangle , $n = 110$), showing the relative (normalized) frequency distribution of the open times. The curves (\bullet — \bullet) (-40 mV) and (\blacktriangle — \blacktriangle) (+40 mV) represent the theoretical exponential distributions for mean open times of 0.36 s and 0.43 s, respectively. In this case the patch apparently only contained one channel.

In one patch for which a relatively long continuous recording was obtained (Fig. 2*a*), the mean single-channel open time was calculated to be 0.93 s whereas the closed time was 0.83 s. We also investigated the effect on the mean open time of changing the membrane potential. In one patch the relative frequency density distribution was compared for membrane potentials of -40 and +40 mV. Figure 2*b* shows the two histograms superimposed on each other. For comparison, the theoretical exponential (Poisson) curves are shown. The two distributions are clearly very similar.

In one series of experiments we investigated the internal calcium dependence of the single-channel currents. Varying the total Ca^{2+} concentration in the bath fluid between 10 μM and 1.25 mM did not markedly affect the current recordings. However, complete removal of bath fluid Ca^{2+} (no Ca^{2+} added, 1 mM EGTA) stopped unitary current activity (Fig. 3). The effect of Ca^{2+} removal was reversible in that the unitary current steps reappeared after Ca^{2+} addition, however, the open time was much shorter and the frequency of opening reduced compared with the first control period. In all five experiments (on five different patches) in which Ca^{2+} was removed from the bath fluid during continued recording, the unitary current steps disappeared.

The channels we have found in the acinar membrane patches seem in many respects similar to the Ca^{2+} -dependent inward current channels recently described in cultured cardiac cells¹² and neuroblastoma cells¹³. This type of channel, so far found in muscle, nerve and gland cells, may be an important feature of many different cells, having a number of roles in various tissues.

The existence of Ca^{2+} -dependent cation permeation pathways in the baso-lateral surface membrane of pancreatic acinar cells was postulated previously on the basis of indirect evidence^{5,14,15}. It is probable that this channel, which has now been directly demonstrated, is important in the stimulus-secretion coupling sequence of acinar cells. Internal Ca^{2+} by simultaneously activating exocytosis and Na^+ entry through

Fig. 3 Ca^{2+} dependency of single-channel currents *a-c*, Consecutive traces from a continuous recording from the same inside-out membrane patch. In this experiment (patch resistance, 3 G Ω) a Na_2SO_4 solution with 1.15 mM MgCl_2 , 4.7 mM KCl, 10 mM glucose and 10 mM HEPES (pH 7.3) was used on both sides. The external (pipette) solution contained 1.28 mM Ca^{2+} . The bathing fluid total Ca^{2+} concentration was 1.28 mM in *a*, while trace *b* was obtained 2 min after changing the bath solution to one without Ca^{2+} but with added EGTA (1 mM). Trace *c* was obtained ~5 min after return of the control solution (1.28 mM Ca^{2+}). The unitary outward current steps seen in *a* disappeared after removal of internal Ca^{2+} , but returned again in *c* after restoration of Ca^{2+} , however, in this period open times were severely shortened. In other experiments recordings were made of inward current steps at membrane potentials of -20 or -40 mV. Removal of Ca^{2+} from the bath fluid always abolished the unitary current steps.

these Ca^{2+} -dependent channels, will couple the two physiologically important processes in the acinar cells, fluid and enzyme secretion, to hormone-receptor interaction. Several other important elements in the stimulus-secretion coupling sequence still remain to be positively identified, that is, the link between hormone-receptor interaction and activation of the Ca^{2+} -effector^{6,14} and the Cl^- (anion) permeation mechanism and its activation¹⁶. Further work with the patch-clamp technique should help in the characterization of the transepithelial transport mechanism and its control.

We thank Dr E. Neher for practical advice and demonstration of the techniques for high-resolution current recording, and Dr I. Schulz for help in the preparation of isolated pancreatic acini. This work was supported by a project grant from the MRC.

Modifier role of internal H^+ in activating the Na^+-H^+ exchanger in renal microvillus membrane vesicles

Peter S. Aronson, Jeannette Nee & Marjorie A. Suhm

Departments of Medicine and Physiology, Yale University School of Medicine, New Haven, Connecticut 06510, USA

The intracellular pH in animal cells is generally maintained at a higher level than would be expected if H^+ were passively distributed across the plasma membrane¹. In a wide variety of cells including sea urchin eggs², skeletal muscle³, renal and intestinal epithelial cells^{4,6}, and neuroblastoma cells⁷, plasma membrane Na^+-H^+ exchangers mediate the uphill extrusion of H^+ coupled to, and thus energized by, the downhill entry of Na^+ . Plasma membrane vesicles isolated from the luminal (microvillus, brush border) surface of renal proximal tubular cells possess a Na^+-H^+ exchanger^{4,5} that seems to be representative of the Na^+-H^+ exchangers found in other tissues. For example, the renal microvillus membrane Na^+-H^+ exchanger, like other Na^+-H^+ exchangers, mediates electroneutral cation exchange^{4,5}, is sensitive to inhibition by the diuretic drug amiloride^{5,8}, and has affinity for Li^+ in addition to Na^+ and H^+ (refs 5, 9). Here we have examined the effect of internal H^+ on the activity of the Na^+-H^+ exchanger in renal microvillus membrane vesicles. Our results suggest that internal H^+ , independent of its role as a substrate for exchange with external Na^+ , has an important modifier role as an allosteric activator of the Na^+-H^+ exchanger. Allosteric behaviour with respect to internal H^+ is a property that would enhance the ability of plasma membrane Na^+-H^+ exchangers to extrude intracellular acid loads and thereby contribute to the regulation of intracellular pH.

Microvillus membrane vesicles were isolated from rabbit renal cortex by a modification¹⁰ of the Mg-aggregation method of Booth and Kenny¹¹. For membranes prepared in this manner, the enrichment in specific activity (final pellet/homogenate) of

luminal membrane markers, such as γ -glutamyl transpeptidase, is >10-fold, whereas those of markers for basolateral membranes and mitochondria, such as $(\text{Na}^++\text{K}^+)\text{ATPase}$ and succinic dehydrogenase, respectively, are <1.0 (refs 10, 11). Electron microscopy reveals that this membrane preparation consists predominantly of right-side-out microvilli with intact core structures¹². Studies using freeze-fracture techniques and immunological methods have also demonstrated that >85% of renal microvillus membrane vesicles are oriented right-side-out¹³.

The effect of internal pH on the Na^+ uptake rate is illustrated in Fig. 1. In this experiment, the vesicles were pre-equilibrated (120 min at 20°C) in media of pH 7.47–6.16 and then the 5-s uptake of 1 mM Na^+ was assayed at external pH 7.26. We have previously shown that equilibration of imposed pH gradients occurs within 120 min in these membrane vesicles⁵. The rate of Na^+ uptake was progressively stimulated as internal pH was lowered. This stimulation of Na^+ uptake by internal H^+ was almost completely abolished by 1 mM amiloride, as earlier observed⁸. Amiloride is a specific, competitive inhibitor for the Na^+-H^+ exchanger in these membrane vesicles⁸. However, the K_i of 3×10^{-5} M for amiloride inhibition of the renal microvillus membrane Na^+-H^+ exchanger is considerably higher than the apparent K_i (10^{-8} – 10^{-7} M) for inhibition of Na^+ channels in tight epithelia¹⁴. Consequently, drug concentrations of 10^{-3} M must be used to abolish Na^+-H^+ exchange in these membrane vesicles⁸. The finding that amiloride-sensitive Na^+ uptake was stimulated by internal H^+ certainly represented the behaviour expected for a Na^+-H^+ exchange process. If the stoichiometry

Fig. 1 Effect of internal pH on Na^+ influx rate. Membrane vesicles were isolated and initially suspended in 200 mM mannitol, 41 mM K^+ , 80 mM HEPES pH 7.47, and then pre-equilibrated for 120 min at 20°C in 157 mM mannitol, 74 mM K^+ , 52 mM Cl^- , 42 mM HEPES pH 7.47 or with isosmotic replacement of mannitol by 9, 17, 26, 35 or 52 mM 2-(*N*-morpholino)ethane sulphonate (MES) at pH 7.19, 6.90, 6.62, 6.40 or 6.16, respectively. The membrane vesicles were then incubated for 5 s at 20°C with 1.0 mM ^{22}Na , 45 mM K^+ , 11 mM Cl^- , 178 mM mannitol, 67 mM HEPES, 10 mM MES pH 7.26 in the absence (○) or presence (Δ) of 1.0 mM amiloride. These incubations were performed in a volume of 50 μl, containing 0.1 μCi ^{22}Na (NEN) and 100–200 μg membrane protein. The incubations were terminated by rapid addition of 3.5 ml of an iced (0–4°C) 'stop' solution consisting of 160 mM KCl, 2.5 mM Tris, 4 mM HEPES pH 7.5. The mixture was immediately poured on a 0.65 μm Millipore filter (DAWP) and washed with an additional 10.5 ml of 'stop' solution. Filters were placed in vials containing 3.0 ml Ready Solv HP (Beckman) and counted by scintillation spectroscopy. Values for the nonspecific retention of radioactivity by the filters were subtracted from the values for the incubated samples. Each datum represents the mean ± s.e. for three determinations. The inset shows a plot of Na^+ influx versus internal H^+ concentration for the pH range 7.47–6.62.

Fig. 2 Effect of internal pH on Na⁺ influx via Na⁺-Na⁺ exchange. Membrane vesicles were pre-equilibrated for 120 min at 20 °C either in 157 mM mannitol, 22 mM K⁺, 42 mM HEPES and 52 mM KCl ('K⁺') or 52 mM NaCl ('Na⁺') at pH 7.47, or in 140 mM mannitol, 22 mM K⁺, 42 mM HEPES, 17 mM MES and 52 mM KCl ('K⁺') or 52 mM NaCl ('Na⁺') at pH 6.90. Using the same filtration method as for Fig. 1, the 5-s uptake of ²²Na was then assayed in the presence of 10 mM ²²Na, 43 mM K⁺, 21 mM Cl⁻, 175 mM mannitol, 63 mM HEPES, 3.5 mM MES pH 7.39 with ('Amil') or without 2.0 mM amiloride. Each datum represents the mean \pm s.e. for three determinations.

of exchange were 1 H⁺ : 1 Na⁺, one would expect the Na⁺ uptake rate to increase linearly with increasing internal H⁺ (first order kinetics) and then to plateau (zero order kinetics) as the internal H⁺ transport site became saturated with H⁺. As indicated in the inset to Fig. 1, however, in the pH range 7.47–6.62 the Na⁺ uptake rate has a greater than first order dependence on the internal H⁺ concentration. This finding raised two possibilities. First, the Na⁺-H⁺ exchanger might possess more than one transport site for internal H⁺. Given that Na⁺-H⁺ exchange in these vesicles seems to be electroneutral^{4,5} with a H⁺ : Na⁺ coupling ratio¹⁵ of 1.0, this would imply that the stoichiometry of Na⁺-H⁺ exchange, rather than 1 : 1, is 2 : 2, 3 : 3, etc. However, arguing against this possibility, the dependence of the Na⁺ uptake rate on the external Na⁺ concentration conforms to simple Michaelis-Menten kinetics^{8,9}. Second, the Na⁺-H⁺ exchanger might possess only a single transport site for internal H⁺ but, in addition, possess one or more modifier sites at which internal H⁺ could bind and thereby activate the exchanger without being transported. Therefore, additional experiments were performed to attempt to demonstrate that internal H⁺, independent of its role as a transportable substrate for exchange, could actually activate the Na⁺-H⁺ exchanger.

Previous studies have suggested that the renal microvillus membrane Na⁺-H⁺ exchanger can mediate Na⁺-Na⁺ exchange⁹. In the experiment shown in Fig. 2, we examined the effect of internal pH on the rate of ²²Na uptake occurring via exchange for internal Na⁺. Membrane vesicles were pre-equilibrated with 52 mM KCl or 52 mM NaCl at pH 7.47 or 6.90, and then the 5-s uptake of 10 mM ²²Na was assayed at external pH 7.39. Because the renal microvillus membrane Na⁺-H⁺ exchanger has no detectable affinity for K⁺ (refs 5, 9), ²²Na uptake into vesicles containing K⁺ should occur only by Na⁺-H⁺ exchange, whereas ²²Na uptake into vesicles preloaded with unlabelled Na⁺ could occur by both Na⁺-H⁺ exchange and Na⁺-Na⁺ exchange. Thus, at any given internal pH, the difference between the ²²Na influx rates of vesicles preloaded with Na⁺ and those preloaded with K⁺ should represent the

component of ²²Na uptake occurring via Na⁺-Na⁺ exchange. As indicated in Fig. 2, the difference between the ²²Na influx rates of Na⁺-preloaded and K⁺-preloaded vesicles was much greater at internal pH 6.90 than at 7.47. That is, internal H⁺ stimulated the component of ²²Na uptake occurring via Na⁺-Na⁺ exchange. This internal H⁺-stimulated Na⁺-Na⁺ exchange was amiloride sensitive, consistent with the concept that it represented a mode of operation of the Na⁺-H⁺ exchanger. Accordingly, this experiment strongly suggested that internal H⁺, independent of its transport role, could indeed activate the Na⁺-H⁺ exchanger. Figure 2 appears to indicate that the amiloride-insensitive Na⁺ influx was not the same in all conditions. However, the actual values for Na⁺ uptake in the presence of amiloride were less than twice the nonspecific retention of ²²Na by the Millipore filters, probably accounting for the observed variability. No consistent relationship between amiloride-insensitive Na⁺ uptake and either internal H⁺ or internal Na⁺ was clearly evident on replications of this experiment.

The renal microvillus membrane Na⁺-H⁺ exchanger can mediate net Na⁺ transport in either direction^{8,15}. When $[Na^+]_o/[Na^+]_i$ exceeds $[H^+]_o/[H^+]_i$, there is net influx of Na⁺ in exchange for internal H⁺, when $[Na^+]_i/[Na^+]_o$ exceeds $[H^+]_i/[H^+]_o$, there is net efflux of Na⁺ in exchange for external H⁺ (ref. 15). In the experiment illustrated in Fig. 3, we tested the effect of internal pH on the rate of net Na⁺ efflux occurring via exchange for external H⁺. Membrane vesicles were pre-equilibrated with 52 mM Na⁺ at pH 7.47 or 6.90, diluted 1 : 100 into a Na⁺-free medium at pH 7.47, and the net efflux of Na⁺ was assayed over the subsequent 30-s period. As indicated in Fig. 3, the net efflux of Na⁺ from vesicles with internal pH 7.47. This internal H⁺-stimulated Na⁺ efflux was amiloride sensitive, consistent with the fact that it represented transport via the Na⁺-H⁺ exchanger. Clearly, the thermodynamic driving force for net Na⁺ efflux via Na⁺-H⁺ exchange ($\Delta\mu_{Na^+} - \Delta\mu_{H^+}$)¹⁶ was less favourable at internal pH 6.90 than at 7.47. Accordingly, the findings in Fig. 3 indicated that internal H⁺ had activated the Na⁺-H⁺ exchanger sufficiently to more than compensate for the inhibitory effect of a diminished driving force for net Na⁺ efflux. This experiment thus provided further support for the concept that internal H⁺ was a potent activator of the renal microvillus membrane Na⁺-H⁺ exchanger.

Because our studies were performed using isolated plasma membrane vesicles rather than intact cells, we can conclude

Fig. 3 Effect of internal pH on Na⁺ efflux. Membrane vesicles were pre-equilibrated for 120 min at 20 °C in 52 mM ²²NaCl, 22 mM K⁺, 42 mM HEPES and either 157 mM mannitol at pH 7.47 (●, ▲, ■) or 140 mM mannitol and 17 mM MES at pH 6.90 (○, △, □). Intravesicular ²²Na content was then assayed before (●, ○) and after 1 : 100 dilution and reincubation of the vesicles for 30 s at 20 °C in 200 mM mannitol, 41 mM K⁺, 80 mM HEPES pH 7.39 with (▲, △) or without (■, □) 1.0 mM amiloride. Each datum represents the mean \pm s.e. for three determinations.

that the observed activation of the Na^+-H^+ exchanger by internal H^+ must have arisen from an interaction at the level of the microvillus membrane. The simplest molecular model to explain our findings is that the Na^+-H^+ exchanger is a transmembrane protein with one or more inwardly facing titratable groups to which internal H^+ can bind and thereby cause a conformational change resulting in an increased transport activity. In experiments not illustrated, we found that the initial rate of Na^+ -dependent glucose uptake in renal microvillus membrane vesicles was not affected by a change in intravesicular pH from 7.47 to 6.90. Thus, whatever the precise molecular mechanism by which internal H^+ activates the Na^+-H^+ exchanger, this activation must not represent a general, nonspecific alteration of microvillus membrane transport function.

In almost all animal cells, a steep inwardly directed Na^+ gradient is maintained across the plasma membrane due to the active extrusion of Na^+ via the $(\text{Na}^++\text{K}^+)\text{ATPase}$. Because $[\text{Na}^+]_0/[\text{Na}^+]_i$ exceeds $[\text{H}^+]_0/[\text{H}^+]_i$ in most conditions, the net driving force acting on plasma membrane Na^+-H^+ exchangers generally favours the net exchange of external Na^+ for internal H^+ . Thus, allosteric activation by internal H^+ would enhance

the ability of plasma membrane Na^+-H^+ exchangers to protect intracellular pH against intracellular acid loads. Recent studies suggest that activation of plasma membrane Na^+-H^+ exchangers may also have a role in such other physiological processes as the regulation of cell volume and the control of cell proliferation^{17,18}. It has been proposed that elevations in intracellular Ca^{2+} may induce this activation¹⁸. We have found that preloading renal microvillus membrane vesicles with 10^{-7} – 10^{-3} M Ca^{2+} has no significant effect on Na^+-H^+ exchange activity (Barrett and P. S. A., unpublished observations). Because of mitochondrial $\text{Ca}^{2+}-\text{H}^+$ exchange, perturbations that induce a rise in intracellular Ca^{2+} can cause a fall in intracellular pH¹. Our studies raise the possibility that the apparent activation of plasma membrane Na^+-H^+ exchangers by intracellular Ca^{2+} could actually represent allosteric activation by intracellular H^+ .

Prostaglandins modulate macrophage Ia expression

David S. Snyder, David I. Beller & Emil R. Unanue

Department of Pathology, Harvard Medical School, Boston, Massachusetts 02115, USA

Prostaglandins are important modulators of inflammation and of humoral and cellular immune responses^{1–8}. In order to evaluate a possible mechanism for the regulation of immune responses we have studied the effects of prostaglandins on the expression of I-region-associated (Ia) antigens by macrophages. The expression of these glycoproteins is essential for macrophages to function as antigen-presenting cells during the induction of immune responses⁹. The synthesis and membrane expression of Ia, however, is not a constitutive property of the phagocyte¹⁰ but is under regulation and a positive regulation of this process is exhibited by activated T cells¹¹. In contrast, a negative regulation is conspicuously found in the neonate where a product from a young replicating macrophage inhibits the expression of Ia by the mature macrophages¹². We show here that prostaglandins of the E series (PGE) are potent inhibitors of the expression of Ia-antigens on macrophages and that thromboxane B₂ (TXB₂) antagonizes the effect of PGE.

The effects of PGE₁ and PGE₂ on the surface Ia expression of cultured macrophages were tested initially. Macrophages were obtained from normal mice or from mice previously injected with proteose-peptone or infected with *Listeria monocytogenes*. Resident macrophages from normal mice contained 5 to 10% Ia-positive cells, those from peptone-induced exudates had 5 to 15% positive, while those from *Listeria*-infected mice had 40 to 80% positive at the start of the culture. We had previously shown that these macrophages rapidly lost the capacity to synthesize Ia, and became Ia-negative after 24 to 48 hours of culture¹⁰. The addition of a lymphokine-containing conditioned medium from immune T cells at the start of the culture resulted in the progressive expression of Ia

so that most of the macrophages were positive after 4 to 7 days regardless of the initial level of Ia-positive cells¹³. This expression of Ia was markedly inhibited by PGE₁ and PGE₂ in a dose-dependent manner with 50% inhibition (I₅₀) at 1.5×10^{-10} M and 8.6×10^{-10} M, respectively (Fig. 1). The dose of PGE required to inhibit Ia was dependent on the amount of T cell-conditioned medium. A fivefold increase in the amount (v/v) of conditioned medium relative to that used in the experiment reported in Fig. 1 did not change the per cent of macrophages that became Ia-positive but resulted in a 10-fold increase in the I₅₀ dose of PGE₁ or E₂. PGE at concentrations of 10^{-7} M or less had no effect on macrophage viability, morphology, adherence properties, or on the per cent expressing IgG Fc receptors, or H-2K glycoproteins (Table 1). Identical results were found testing resident macrophages or those from exudates induced with peptone or following *Listeria* infection. It appears that PGE inhibition is associated with suppression of Ia biosynthesis (unpublished observation). The time of addi-

Table 1 Effects of PGE₂ on expression of macrophage surface proteins

Treatment		% Of cells positive for		
Lymphokine	PGE ₂	Ia	H-2K	Fc receptors
–	–	1	78	>98
+	–	37	83	>98
+	10^{-9} M	18	82	>98
+	10^{-7} M	5	82	>98
+	10^{-6} M	2	77	>98

Macrophages were prepared and cultured exactly as described in Fig. 1. Macrophages were cultured for 6 days with 2% conditioned media (lymphokine). Prostaglandins were added during the last 2 days of culture. Ia expression was assessed by immunofluorescence as in Fig. 1. H-2K expression was similarly determined using a monoclonal anti-H-2K^b antibody (clone line 11–4.1, from Dr L. Herzenberg), followed by fluorescein-labelled F(ab')₂ rabbit anti-mouse immunoglobulin. The cells were fixed after staining for H-2K. Fc receptors were detected by standard techniques of erythrocyte rosetting, using sheep red blood cells coated with rabbit IgG antibody.

tion of PGE to the cultured macrophages was important. Addition for only the first 2 days retarded the appearance of Ia-positive cells by 1 to 2 days but did not affect the ultimate level of Ia expression, addition at the time when most macrophages were Ia-positive resulted in loss of expression within 48 h.

As PGE is known to increase intracellular cyclic AMP levels in macrophages¹⁴, we tested the effects of cyclic AMP analogues

Fig. 1 Suppression of macrophage Ia expression by PGE₁ (●), PGE₂ (○), and dibutyryl cyclic AMP (□) in culture. Macrophages were obtained from the peptone-elicited peritoneal exudates (1 ml 10% proteose-peptone, 3 days before cells were collected) of adult A/St mice previously infected with 2×10^4 live *Listeria monocytogenes* organisms intraperitoneally²². The exudates were collected 3 to 4 days later by lavaging with 5 ml of Hank's balanced salt solution containing 0.6% g bovine serum albumin, 10 mM HEPES, and 10 units per ml heparin. Peritoneal exudate cells (2×10^5) were plated on glass coverslips placed in flat-bottom, Costar wells, in 1 ml of RPMI 1640 containing 5% fetal calf serum for 2.5 h at 37°C, 5% CO₂, then non-adherent cells were washed off. The medium was replaced with RPMI 1640 containing 10% fetal calf serum, plus or minus 2% conditioned media from a *Listeria*-immune T-cell line¹³. This medium was washed off on day 3 or 4 and replaced with fresh RPMI with or without the drugs. Prostaglandins were the gift of Dr John Pike (Upjohn). They were stored as stock solution at 10 mg per ml of absolute ethanol at 4°C, then diluted before each experiment with a 0.2 M phosphate buffer. On day 4 or 5, the macrophages were given a 24-h pulse of 5×10^6 heat-killed *Listeria* organisms and were then fixed in 1% paraformaldehyde and stained for surface Ia on day 5 or 6²². Cells on glass coverslips were exposed to a monoclonal anti-I-A^k antibody (clone 10-2-16) (5 µg per ml) mixed with a 1:5 dilution of decomplexed normal rabbit serum, at 4°C for 15 min. Fluorescent labelling was carried out as described in ref. 22. The % of Ia-positive macrophages was determined by counting 200 cells with a fluorescent microscope. Macrophages cultured in RPMI alone were 0 to 5% Ia-positive, those cultured in T-cell lymphokine were 40 to 80% positive. Per cent suppression was calculated as

$$\frac{\% \text{ Ia-positive control} - \% \text{ Ia-positive experimental}}{\% \text{ Ia-positive control} - \% \text{ Ia-positive background}} \times 100$$

Data represent the mean \pm s.e.m. These results are similar to those from radiolabelled antibody binding.

or agonists. Figure 1 shows that dibutyryl cyclic AMP inhibited Ia expression with an I_{50} of 9×10^{-7} M. (In other experiments, isoprenaline inhibited in the dose range of 10^{-5} M to 10^{-6} M and theophylline in the range 10^{-3} to 10^{-4} M.)

The concentrations of PGE inhibiting Ia are well within the physiological range found in tissues, which varies from about 10^{-11} M in basal states¹⁵ to as high as 10^{-7} M in inflammatory sites¹⁶. The inhibitory effects of PGE on macrophage Ia could be shown *in vivo* under two circumstances (Table 2). First, intraperitoneal injection of PGE₁ inhibited the lymphokine-induced development of peritoneal exudates rich in Ia-positive macrophages¹¹. Second, injection of indomethacin not only augmented the response to lymphokines but increased the basal number of Ia-positive macrophages as well. Further indication of the role of PG *in vivo* comes from an earlier study in which we showed that repeated injection of resident peritoneal macrophages—the phagocyte population producing the highest basal level of PGE¹⁷—interfered with the lymphokine-induced development of Ia-positive macrophages¹². Additionally, there are reports that indomethacin stimulates monocytopoiesis resulting in increased numbers of peripheral blood monocytes and tissue macrophages¹⁸ and that PGE inhibits monocytopoiesis¹⁹. Taken together, these examples suggest that PGE-mediated inhibition of Ia expression may be one of several regulatory effects exerted by arachidonic acid metabolites on the macrophage lineage.

Another important aspect of PGE regulation of Ia expression is the possibility that other arachidonic acid metabolites can antagonize the effects of PGE. We, therefore, looked at the effect of TXB₂, a stable metabolite of thromboxane A₂. Thromboxane A₂, which is produced by activated macrophages²⁰, has been shown to lower intracellular cyclic AMP levels²¹. Although TXB₂ is known to be less active than thromboxane A₂ it exerted an effect in our system. Figure 2 indicates that TXB₂ was a surprisingly potent antagonist to the effects of PGE₂ but had a small and inconsistent effect on Ia expression in the absence of T-cell stimulation. PGE₁ had no effect, either *in vitro* or *in vivo*. We are now investigating products of the lipoxygenase pathway. In preliminary studies, we have tested three monohydroxyicosatetraenoic acids (5-HETE, 11-HETE, and 15-HETE provided by Dr E. Goetzl). In the presence of lymphokines, these lipoxygenase metabolites increased the number of Ia-positive macrophages by 13 to 60%.

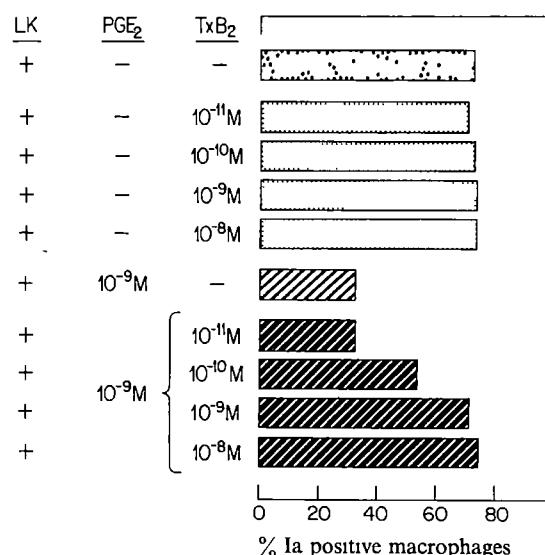

Fig. 2 TXB₂ and PGE₂ are antagonists. Macrophages were prepared and cultured as described in Fig. 1. On day 3, RPMI plus or minus 2% T-cell lymphokine (LK) was replaced with fresh RPMI containing PGE₂, TXB₂, or both. Cells were pulsed with heat-killed *Listeria* organisms on day 4, then fixed and stained for Ia on day 5.

Table 2 Effects of indomethacin and PGE₁ on peritoneal exudate macrophages

Experiment no.	Injected material	Macrophages per mouse ($\times 10^{-5}$)	Ia-positive (%)	Ia-positive macrophages per mouse ($\times 10^{-5}$)
1	Indomethacin, 50 μ g in 5% ethanol 5% Ethanol	10.0	5	0.5
		24.3	28	7.0
		19.3	8	1.5
2	Indomethacin, 50 μ g in 5% ethanol Lymphokine, 1:20 Indomethacin, 50 μ g, plus lymphokine, 1:20	5.5	9	0.5
		26.0	23	6.0
		11.6	38	4.4
		26.2	50	13.1
3	Lymphokine, 1:2 Lymphokine, 1:2, plus 15-methyl PGE ₁ , 1 μ g	8.6	4	0.3
		30.2	35	10.6
		26.0	15	3.9
4	15-Methyl PGE ₁ , 1 μ g PGE ₁ , 50 μ g Lymphokine, 1:2 Lymphokine, 1:2, plus 15-methyl PGE ₁ , 1 μ g Lymphokine, 1:2, plus PGE ₁ , 50 μ g	8.8	4	0.35
		24.8	9	2.2
		15.4	7	1.1
		35.0	45	15.8
		57.8	8	4.6
		47.5	5	2.4

A/St or B10.A adult mice were injected intraperitoneally with 0.5 ml of the materials every 12 h, six times, as previously reported¹¹. Peritoneal exudate cells were collected 12 h after the last injection, then plated on coverslips in RPMI for 2.5 h as described in Fig. 1. Non-adherent cells were washed off and counted, and the per cent adherent cells was calculated. Adherent cells were fixed and stained for Ia as described in Fig. 1.

Overall, our results suggest that prostaglandins can regulate the expression of Ia antigens on macrophages induced by lymphokines (Fig. 1, Table 1) as well as the T-cell-independent development of the basal levels of Ia-positive macrophages in tissues. Our results also suggest that the relative concentration of different arachidonic acid metabolites influences the level of Ia expression (Fig. 2). The finding that indomethacin increased Ia expression *in vivo* in the absence of exogenous lymphokine suggests either that PGE interferes with the spontaneous expression of Ia by some macrophages or that it influences the response to environmental stimuli. The basal level of Ia-positive macrophages, however, was not inhibited by injection of PGE (Table 1), implying that there may be some heterogeneity among macrophages with respect to PGE sensitivity. Finally, we suggest that the regulation of Ia expression by prostaglandins could be an important control mechanism in the inductive phase of immune responses. We have recently found that the loss of Ia by macrophages after exposure to PGE is associated with reduced antigen presentation to immune T cells (unpublished observations).

University of Ottawa, Ottawa, Canada K1H 8M5

Pluripotent murine embryonal carcinoma cells can differentiate in culture into many tissue types similar to those normally found in early embryos¹ and may be useful in investigating some developmental events^{1,2}. Central to our understanding of embryonic development are explanations of cellular determination, that is, the commitment of early embryonic cells to form divergent cell types. Of relevance is recent work with the F9 line of embryonal carcinoma cells which suggests that certain extra-embryonic cell types are specifically formed following treatment of undifferentiated cells with drugs^{3,4} and the manipulation of culture conditions⁵. We report here that the P19 line of embryonal carcinoma cells⁶ may provide an analogous system in which drugs can be used to manipulate the formation of tissues which normally comprise the fetus. In the presence of dimethyl sulphoxide (DMSO) aggregates of P19 cells differentiate rapidly to form large amounts of cardiac and skeletal muscle but no neurones or glia. We have previously shown that in the presence of high concentrations of retinoic acid ($>5 \times 10^{-7}$ M), aggregates of these same cells develop into neuronal and glial tissues but not muscle⁷. Thus, drugs can be used to generate two quite different spectra of embryonic tissue types from the same population of embryonal carcinoma cells.

P19 is a euploid (40:XY) embryonal carcinoma cell line derived from a teratocarcinoma induced in C3H/He strain mice⁶. For the experiments described below, we used P19S1801A1, a ouabain-resistant and 6-thioguanine-resistant subclone of P19 isolated without mutagenesis. Suspensions of dispersed cells were plated onto bacterial-grade plastic surfaces to which cells do not adhere⁸. Cells adhere to each other to form small aggregates. These aggregates were cultured in suspension for 4–5 days in the presence or absence of DMSO.

They were then plated into tissue culture-grade plastic dishes.

In the absence of drug, the plated aggregates contained undifferentiated embryonal carcinoma cells along with small numbers of extra-embryonic endodermal cells⁷ (Fig. 1a). The presence of DMSO in the culture medium produced effects which became clear 1–2 days after plating, that is, 6–7 days after initiation of the experiment. In cultures exposed to 0.25% (v/v) DMSO, most plated aggregates contained embryonal carcinoma cells, rhythmically contracting muscle and fibroblast-like cells. At concentrations of 0.5, 0.75 and 1.0% DMSO, none of the plated aggregates contained embryonal carcinoma cells (identified by morphology), virtually all contained areas of rhythmically contracting muscle, and all contained cells with fibroblast-like morphology (Fig. 1c). By 10–12 days the amount of contracting muscle had increased (Fig. 1d, e). Also at this time many of the DMSO-treated aggregates developed areas of bipolar myoblasts which fused into myotubes (Fig. 1f). These myotubes were usually non-contractile but often developed spontaneous twitching activity by 14 days.

Fig. 1 Phase contrast photomicrographs of live teratocarcinoma cells. The conditions for cell culture^{7,12} and aggregation⁸ have been described previously. Cell aggregates were formed from a stock culture of P19S1801A1 cells and parallel cultures were carried in: *a*, normal medium (α -medium plus 10% fetal bovine serum¹²); *b*, in medium containing 5×10^{-7} M retinoic acid; and *c–f*, in medium containing 0.5% (v/v) DMSO. Aggregates were cultured in suspension in bacterial-grade Petri dishes for 5 days before being plated on to tissue culture-grade plastic surfaces. Photographs were taken 2 days (*a–c*) or 9 days (*d–f*) later. *a*, Untreated aggregates contain embryonal carcinoma and a few extra-embryonic endoderm cells (arrow). *b*, Aggregates of cells which had been cultured in the presence of 5×10^{-7} M retinoic acid contain neurones and astrocyte glial cells⁷. *c–f*, Aggregates cultured continuously in the presence of 0.5% DMSO contain small areas of rhythmically contracting cardiac muscle (arrows in *c*) which become more extensive with time (*d*). At higher magnification are: *e*, areas of rhythmically contracting mononucleate cardiac muscle and, *f*, multinucleate skeletal muscle. Scale bars, 200 μ m.

Fig. 2 Electron micrographs of some of the tissues formed in DMSO-treated cultures. *a*, A section through cardiac muscle shows bundles of thick and thin filaments in longitudinal section (arrows), glycogen granules (arrowhead) and numerous mitochondria. *b*, A section through a multinucleate myotube shows the thick and thin filaments in cross section (arrow) and glycogen (arrowhead). Many of the non-muscle cells in these cultures secreted collagen (*c*) which was often seen forming part of an intercellular matrix. Scale bars, 0.5 μ m.

Electron microscopy of the cells in DMSO-treated cultures indicated that the rhythmically contracting cardiac muscle cells contained glycogen granules, large numbers of mitochondria, and numerous areas of thick and thin filaments which were not organized into mature myofibrils (Fig. 2a). The multinucleate skeletal muscle cells were similar in appearance (Fig. 2b). Thus both muscle types seemed to be immature. Many of the non-muscle cells had abundant rough endoplasmic reticulum and some were surrounded by extracellular matrix which included collagen fibres (Fig. 2c).

The DMSO-treated aggregates of P10S1801A1 cells developed muscle but neither neurones nor glia. Treatment of the same cells with retinoic acid resulted in the development of neurones (Fig. 1b), glial cells, fibroblast-like cells, but no muscle. Cultures exposed to both retinoic acid (5×10^{-7} M) and DMSO (0.5 or 1.0%) developed as if exposed only to retinoic acid, that is, neurones and glia but no muscle were formed.

Differentiated cultures contained more actin than did untreated cultures (Table 1). Much of the actin in DMSO-treated cultures was α -actin, the type present only in skeletal and cardiac muscle cells⁹. Muscle-specific myosin was also detected in both cardiac and skeletal muscle by immunofluorescence using monoclonal antibodies directed against muscle myosin. About 15% of all cells were muscle myosin positive in these cultures by 8 days but none were detected in untreated or in retinoic acid-treated cultures.

When 10 μ M adrenaline was added to DMSO-treated cultures, the cardiac muscle responded by a 2–2.5-fold increase in contraction frequency and some previously quiescent areas of the culture were stimulated into rhythmic activity. Therefore β -adrenergic receptors were present. Such receptors are apparently acquired by cardiac muscle after the acquisition of spontaneous contractility¹⁰.

DMSO was not demonstrably cytotoxic to the P19S1801A1 cells at concentrations effective in differentiation experiments. Figure 3 shows that the efficiency of colony formation was unaffected by DMSO at concentrations up to 1.0%. Virtually all colonies formed in DMSO contained only embryonal carcinoma cells. In other experiments, monolayers of cells were cultured for 20 days in 1% DMSO without change in growth rate or morphology. At the end of this 20-day period, the DMSO-treated cells were aggregated in the presence or absence of DMSO (0.5%). Those aggregates formed in the absence of DMSO did not differentiate while those cultured in the drug formed muscle and fibroblasts in the usual way. Thus, it seems that the DMSO had no effect on the P19S1801A1 cells cultured as monolayers and that both the drug and cell aggregation are necessary for muscle differentiation. DMSO could be removed after 2–3 days but cardiac muscle still developed at 6–7 days as in the continuous presence of the drug.

The effects of DMSO described above were observed not only on P19S1801A1 cells, but also on the parental P19 cells and on all of the subclones from this line which were tested. However, DMSO had no effect on the differentiation of the embryonal carcinoma cell lines F9¹¹, OC15S1¹² and C86S1¹² whereas some clones of P10 cells¹³ appear to form an excess of neurones in the presence of DMSO (G. D. Paterno and M.W.M., unpublished). Variation has also been observed in the response of different embryonal carcinoma lines to retinoic acid^{3,7} and to aggregation in the absence of drugs^{1,2}.

DMSO is an inducer of Friend cell differentiation¹⁴ as are 6-thioguanine¹⁵, butyrate¹⁶ and ouabain¹⁷. The effects reported above for DMSO have also been observed with non-toxic concentrations of 6-thioguanine and butyrate but not with ouabain. Another Friend cell inducer, hexamethylene bisacetamide (HMBA), has previously been shown to influence the differentiation of some other embryonal carcinoma cell lines^{18,19} but we have not tested this compound with P19 cells.

Many papers have reported the formation of a limited range of cell types following spontaneous or induced differentiation of lines of teratocarcinomas and of embryonal carcinoma cells^{20–23}, but it is not clear whether this is the result of differential selection or of the occurrence of a limited number of determinative events. We think it is unlikely that differential selection can account for our observations because: (1) the cells

Fig. 3 The efficiency of colony formation of P19S1801A1 embryonal carcinoma cells in the presence of DMSO indicates the absence of toxicity at concentrations of less than 1% (v/v). About 200 cells were introduced into replicate 60-mm diameter dishes containing various concentrations of DMSO dissolved in α -medium supplemented with 10% fetal bovine serum and 10^{-6} M β -mercaptoethanol. Incubation was for 8 days at 37°C. All colonies consisted of cells with embryonal carcinoma morphology. Those colonies formed in 1.5% DMSO were smaller than control colonies, indicating that at these concentrations, the rate of cell proliferation was decreased.

Table 1 Presence of α -actin in DMSO-treated cultures

Treatment	Total actin*	α -actin*	% Muscle actin
Untreated, day 7	1.91 \pm 0.07	0.16 \pm 0.02	8.4
Retinoic acid, day 7	2.31 \pm 0.03	0.30 \pm 0.02	13.0
DMSO, day 7	2.62 \pm 0.15	0.52 \pm 0.01	19.8
DMSO, day 11	3.05 \pm 0.14	0.68 \pm 0.02	22.3

Aggregated cultures were prepared as described in Fig. 1 legend. Two days after plating (day 7) or 6 days after plating (day 11) the cultures were collected for analysis. The DMSO-treated day 7 culture contained rhythmically contracting but not multinucleate muscle. By day 11 both muscle types were present. Protein and peptide isolation was carried out as previously described²⁴ except for the use of trypsin instead of chymotrypsin for peptide generation. The actin contents were calculated by measuring the amounts of material which co-purified during electrophoresis at pH 6.5, 2.1 and 3.5 with tryptic peptides generated from muscle actin. Total actin values were calculated from the amounts of radioactive material co-migrating with the two chemically modified peptides CmCys-Asp-Ile-Asp-Ile-Arg and CmCys-Phe. All known actins contain peptides which should co-purify with these two. α -Actin values were calculated from the amount of material co-purifying with an 18-residue CmCys-containing peptide generated from the N-terminal region of α -actin. Actins from other tissues differ from α -actin in this region⁹ so should not co-purify with this peptide. Total actin is higher in differentiated than in undifferentiated cultures and there is more muscle-specific α -actin in DMSO-treated cultures. The 8–13% of muscle actin present in untreated and in retinoic acid-treated cultures may represent a background of radioactive label derived from non- α -actin peptides which co-purify with the legitimate peptide.

* mg actin per 100 mg total protein.

did not differentiate into embryonic cell types in the absence of drugs, (2) the cell types formed in DMSO-treated cultures were substantially different from those formed by the same cells in parallel cultures exposed to retinoic acid, (3) neither drug appeared to be toxic, (4) all subclones responded to both drugs, (5) the drugs were effective even when cultures were exposed to them for 48 h at the beginning of an experiment, and (6) DMSO did not inhibit the formation of neurones in cultures exposed to both retinoic acid and DMSO. The simplest interpretation of these data seems to be that each drug acts by 'inducing' uncommitted embryonal carcinoma cells to differentiate along a limited number of developmental avenues. If the drugs act by bringing about intracellular changes which mimic the results of certain embryonic decisions, it may be possible to use the drugs to identify parts of the cellular decision-making apparatus.

This work was supported by grants from the NCI of Canada and the MRC of Canada. We thank Irwin Schweitzer and Kem Rogers for their help. Antibody to glial fibrillar protein was the gift of Dr V. Kalnins and antibody to muscle-specific myosin was provided by Drs D. Morgenstern, D. A. Fischman and P. Merrifield.

Carbohydrate antigens on the surface of mammalian cells have recently gained renewed interest because some are specifically expressed at certain stages of cellular differentiation¹⁻⁴. Most of the useful antibodies detecting such carbohydrate antigens have been monoclonal antibodies produced by the hybridoma technique using whole cells as the immunogen¹⁻³ or the antibodies in the sera of some of human patients⁴. Here we report that an antiserum raised against an unusual carbohydrate linkage prepared by organic synthesis can preferentially react with certain tumour cells. Thus, an antiserum against the Fucal→3Gal linkage reacted with human colon adenocarcinoma cells and murine teratocarcinoma cells but reacted only with severely restricted regions in normal tissues.

Fig. 1 Ouchterlony double-diffusion analysis on the specificity of the rabbit antiserum against 3'-fucosyllactose-PIP-BSA. The antigen (0.4 mg) was mixed with Freund's complete adjuvant and injected into the footpads of a rabbit. After 3 and 5 weeks, the rabbit received two booster injections using half the amount of antigen. The rabbit was bled 10 days after the last immunization. The double-diffusion analysis was performed in 1% agar gel containing 2% Triton X-100, 0.15 M NaCl, 50 µg ml⁻¹ of phenylmethanesulphonyl fluoride and 0.05% sodium azide in 0.01 M Tris-HCl buffer, pH 7.6, on a slide glass. The central well contained the antiserum and the peripheral wells contained 20 µg each of the following materials: a, 3'-fucosyllactose-PIP-BSA, b, 4'-fucosyllactose-PIP-BSA, c, 6'-fucosyllactose-PIP-BSA, d, lactose-PIP-BSA, e, BSA. Preparation of 4'-fucosyllactose and 6'-fucosyllactose has been described elsewhere¹². Carbohydrate contents of the PIP-BSA derivatives were determined by the phenol-H₂SO₄ reaction¹³, and were found to be 20 mols per mol of BSA in 3'-fucosyllactose-PIP-BSA, 25 mols per mol of BSA in the 4'-fucosyl compound and 23 mols per mol of BSA in the 6'-fucosyl compound.

Fig. 2 Reaction of the serial tissue sections from a mouse uterus with the anti-Fucal→3Gal serum or with UEA-1. The organs were taken from a 3-month-old female 129/SV mouse, quick frozen and sectioned in a cryostat. The section was fixed for 1 min with acetone. a, Immunofluorescence staining with the antiserum showing the presence of the antigen in the squamous epithelium of the uterine cervix. The section was incubated with the antiserum diluted 20-fold with phosphate-buffered saline and then with FITC-conjugated F(ab')₂ fragment of goat anti-rabbit IgG (Cappel), and was observed by a fluorescence microscope using epillumination (Olympus, Model BH-RFL-LB). ×80. Very similar results were also obtained using BALB/c, ICR and ddY mice. No staining was observed in control experiments where rabbit non-immune serum, rabbit anti-BSA or rabbit anti-lactose-PIP-BSA was used instead of the specific antiserum. b, Staining with FITC-UEA-1. The tissue sections were incubated with 25 µl of FITC-UEA-1 at 1 mg ml⁻¹. ×80.

3'-Fucosyllactose (Fucal→3Galβ1→4Glc) was synthesized as described previously⁵, converted to the *p*-isothiocyanate-phenethylamine (PIP) derivative and coupled with bovine serum albumin (BSA) according to Smith *et al.*⁶. The product (3'-fucosyllactose-PIP-BSA), which contained 20 mols of 3'-fucosyllactose per mol of BSA, was injected into a rabbit. The resulting antiserum formed a sharp precipitation line with the antigen, but not with BSA, lactose-PIP-BSA, 4'-fucosyllactose-PIP-BSA nor with 6'-fucosyllactose-PIP-BSA (Fig. 1). Furthermore, these BSA derivatives without the Fucal→3Gal linkage were unreactive to the antiserum even in a binding assay, in which Sepharose coupled with the derivatives were stained with the antiserum by indirect immunofluorescence technique used in Fig. 2.

The reactivity of the antiserum to normal cells was also studied. Frozen sections of organs of adult mice were incubated with the diluted antiserum, and then fluorescein isothiocyanate (FITC)-labelled F(ab')₂ fragment of goat anti-rabbit IgG. We found that the antiserum stained squamous epithelium of the uterine cervix (Fig. 2a), ciliated border of the oviduct, epithelium of the bronchus, ependyma lining the ventricles of the brain and spermatocytes of the testis. The following organs were negative for the antigen: small intestine, proximal and distal colons, liver, spleen, kidney, epididymis, ovary and endometrium. The extremely restricted distribution of the antigen in the mouse suggests that the antiserum does not cross-react with H antigen whose determinant is Fucal→2Gal linkage⁷ or with SSEA-1 whose determinant involves Fucal→3GlcNAc linkage^{2,3}. SSEA-1 is known to be present in the epididymis and in the endometrium but not in squamous epithelium of the uterine cervix. It is also present in a portion of epithelial cells of the oviduct but not in ciliated border of the oviduct⁸. H antigen detected by staining with FITC-conjugated *Ulex europaeus* agglutinin 1 (UEA-1) was expressed in a variety of the adult tissues including endometrium of the uterus (Fig.

2b), small intestine, proximal and distal colons. Furthermore, the present antiserum did not stain erythrocytes of a number of human subjects whose blood types included H and Le^a. The failure to react with Le^a erythrocytes excluded the possibility that the antiserum cross-reacts with Fuc α 1 \rightarrow 4GlcNAc linkage⁷. From all these results, we propose that the antiserum specifically recognized Fuc α 1 \rightarrow 3Gal linkage. The antigen recognized by the antiserum was termed as FG3 antigen.

The antigen was detected in human colonic adenocarcinoma (Fig. 3a). The staining reaction was inhibited by 0.2 M 3'-fucosyllactose, but not by 0.2 M lactose, 0.2 M fucose, nor by 10 mg ml⁻¹ BSA. So far frozen sections of 17 human colonic adenocarcinoma have been examined. Of these, seven cases expressed the antigen in intracytoplasmic granules (Fig. 3a) and five cases expressed it along the cell apex. As the antigen was present not only on the luminal surface of the carcinoma but also in the invasive nests of the carcinoma in deep layers of intestinal wall (Fig. 3a), we considered that the antigen was produced by the carcinomas themselves. Only tumour cells

Fig. 3 Immunofluorescent staining of a human colonic adenocarcinoma using the anti-Fuc α 1 \rightarrow 3Gal serum. The tissue section was prepared from surgically removed specimen of a human colon adenocarcinoma of 44-year-old female Japanese patient (Blood group B type). Staining was performed as described in the legend of Fig. 2. *a*, Cancerous lesion. $\times 160$. *b*, Non-neoplastic mucosa of this patient. $\times 80$.

within the colonic tissue section were positive for the antigen (Fig. 3b). Antiserum against lactose-PIP-BSA did not react with the tumour region. FG3 antigen was undetectable in tissue sections of normal human duodenum, liver, gallbladder, pancreas, lung, thyroid, thymus, lymph node, muscle, connective tissue and blood vessels. Although further studies are needed to examine the distribution of the antigen in other normal tissues and also in other neoplastic conditions, the tumour-specific expression of the antigen in human colon is of significant interest.

As stem cells of teratocarcinoma are known to express unusual fucosyl glycopeptides^{9,10}, we examined the expression of FG3 antigen in a stem cell line, F9 and found it (Fig. 4). The antigen was also detected on stem cells of teratocarcinoma OTT6050 and on another stem cell line, STT-M. Therefore, some embryonic antigens expressed on teratocarcinoma stem cells may contain this unusual fucosyl linkage.

However, the Fuc α 1 \rightarrow 3Gal linkage is not found in glycoproteins and glycolipids isolated from diverse sources, but its presence has been reported in mixtures of higher homologues of human milk oligosaccharides¹¹. The present results suggest

Fig. 4 Immunofluorescent staining of F9 embryonal carcinoma cells using the anti-Fuc α 1 \rightarrow 3Gal serum. F9 cells were cultured on a glass coverslip in Dulbecco's modified minimum essential medium containing 15% fetal calf serum. Cells on the coverslip were stained as described in the Fig. 2 legend, except that acetone treatment was omitted. *a*, Specific staining. $\times 120$. *b*, Control staining using non-immune serum. $\times 120$. *c*, Phase contrast microscopic observation of the cells shown in *a*. $\times 120$. *d*, Phase contrast microscopic observation of the cells shown in *b*. $\times 120$.

that the unusual fucosyl linkage is expressed in certain cancerous and embryonic tissues. It is possible that such carbohydrate linkages are involved in intercellular communication during early embryonic life but are expressed aberrantly in certain cancerous cells.

We thank Miss Kumiko Sato for secretarial assistance.

In vivo* surveillance of tumorigenic cells transformed *in vitro

John Leslie Collins, Paul Q. Patek & Melvin Cohn

Salk Institute, PO Box 85800, San Diego, California 92138, USA

Any theory of surveillance against cancer requires that cells susceptible to host protective mechanisms exist as intermediates on the pathway from normal to cancer¹. The failure to demonstrate a significant frequency of such intermediates as a result of chemical carcinogenesis has cast serious doubt on the validity of the surveillance hypothesis². Here we report the conditions in which such intermediates can be identified as the major class of transformed cells resulting from *in vitro* chemical carcinogenesis of a cloned fibroblastic cell line.

We have previously reported the isolation and identification of cells that are intermediates between normal and cancerous cells³. We treated cloned cell lines (N-type) *in vitro* with

Table 1 Classification of cells by their tumorigenic potential

Type	Growth as a tumor in:	
	ATxFL mice	normal mice
N	-	-
I	+	-
C	+	+

chemical carcinogens and selected transformants by their anchorage-independent growth in agarose (Table 1). These transformants were then tested for their ability to grow as tumours in normal and surveillance-deficient mice; thymectomized, irradiated, and fetal liver restored (ATxFL). We found: (1) a correlation of 0.9 between the ability of these cells to grow in agarose and as tumours in ATxFL mice; (2) two classes of transformants, those which were tumorigenic in ATxFL mice but not in normal mice (I-type) and those which were tumorigenic in both (C-type); and (3) 20% of the chemically transformed cells were of the I-type and 80% of the C-type. The existence of I-type cells shows that a surveillance mechanism operates in normal mice to prevent the growth of some transformed cells and this surveillance mechanism is deficient in ATxFL mice.

The principle of the experiment described here is to treat N-cells *in vitro* with a chemical carcinogen and select transformants, not by their ability to grow in agarose, but by their ability to grow as tumours in ATxFL and normal mice. By testing the tumorigenic potential of carcinogen-treated N-cells in ATxFL and normal mice we were able to estimate the frequency with which transformation results in the I or C phenotype. Further, we demonstrated that transformants of N-cells selected for their tumorigenicity were anchorage-

Table 2 The tumorigenic potential of N-cells treated *in vitro* with BPE

Treatment	No. of dishes containing cells which were:		Tumorigenic only in ATxFL mice (I-type)	Tumorigenic in ATxFL and normal mice (C-type)

BPE	1	7		1
Expt 3				
THF control	10	1		0
BPE	9	8		7

The N-cell line, B/C-N 7.1, was grown in Dulbecco's modified Eagle's minimum essential medium (DMEM) plus 10% fetal calf serum (FCS). Cells (10^6 per 60 mm dish) in DMEM were treated with benzo(a)pyrene-*trans*-7,8-dihydrodiol-9,10-epoxide (BPE; supplied by NCI) dissolved in THF. The final concentration of BPE was 20 ng ml^{-1} in 1% THF. The control dishes were treated with DMEM containing 1% THF. One week later the cells were removed from the dishes with trypsin, washed, and injected into two normal mice and two mice which had been thymectomized as adults, lethally irradiated (750 rad) and restored with 10^7 syngeneic liver cells from 14-15-day-old-fetuses (ATxFL). Animals were examined weekly for tumours, which appeared between 45 and 120 days after injection. Tumours were excised when they reached approximate volumes of $1-2 \text{ cm}^3$, mechanically dissociated, and re-established in *in vitro* culture. In all experiments tumours were derived from the injected parental N-cell populations and not from *in situ* transformation of host cells as shown by the fact that all the excised tumours were hypoxanthine-guanine phosphoribosyltransferase-negative, a marker introduced into the parental N-cells.

independent, the converse of our previous experiment³ where cells selected for anchorage independence were tumorigenic. Thus, starting with this cloned non-tumorigenic, anchorage-dependent cell line, not only does selection for anchorage independence result in tumorigenicity but selection for tumorigenicity results in anchorage independence.

Benzo(a)pyrene epoxide (BPE) dissolved in tetrahydrofuran (THF) was added to culture dishes containing 10^6 cloned N-cells in media without serum. The final concentration of BPE was 20 ng ml^{-1} , the medium contained 1% THF. Serum was added after 1 h of exposure to BPE; after 1 week the cells were collected, counted, and 10^6 cells injected into ATxFL mice (experiment 1, Table 2) or ATxFL and normal mice (experiments 2 and 3, Table 2). As a control, an equal number of N-cells treated only with medium containing 1% THF were injected into mice.

Two points emerge from the results shown in Table 2. First, BPE dissolved in THF is much more effective than THF alone in transforming N-cells to grow as tumours; 46/57 dishes treated with BPE plus THF resulted in tumours compared with only 2/20 in the THF-treated dishes. Assuming that the number of transformants per dish follows a Poisson distribution, then the frequency of transformation by BPE plus THF is 40 times that of THF alone. Second, N-cells transformed by BPE can be divided into two classes based on their tumorigenicity, I-type growing as tumours in ATxFL but not normal mice and C-type growing as tumours in both ATxFL and normal mice. In the two experiments where the I or C phenotype of the transformants in 23 dishes was determined, 15 were I-type and 8 C-type. From the distribution of these data, I-type transformants appear at least three times more frequently than C-type.

The excised tumour cells were re-established in culture and then analysed for their ability to grow anchorage-independently. All of them expressed anchorage-independent growth (colony forming efficiencies³ between 1 and 30%) relative to the parental anchorage-dependent N-line (colony forming efficiency $<0.01\%$) from which they were derived. The plating efficiency in agarose was independent of whether the tumour cells were derived from ATxFL or normal mice or whether tumours resulted from the injection of BPE-treated N-cells or from the few tumours formed by injecting control THF-treated N-cells. There is no correlation between the colony-forming efficiency of a transformant and its I or C phenotype.

The fact that all tumours, when re-established in culture, are anchorage-independent is complementary to our previous observation that anchorage-independent fibroblasts are tumorigenic³. Thus, for fibroblastic cell lines, tumorigenicity and anchorage independence are coordinately expressed whether the selection pressure used to isolate them is anchorage independence or tumorigenicity.

The major difference between the transformants selected by their ability to grow as tumours and those selected by their ability to grow in agarose is the frequency with which the transformations result in the I or C phenotype. By using transformants selected for their expression of anchorage independence, we previously estimated the frequency of transformation resulting in a cell of the I-type to be $\sim 20\%$ (ref. 3). In the experiments reported here the frequency of I-type transformants is much greater than 50%.

There are two possible explanations for the differences in the proportion of I- and C-type transformants in these two experiments. First, the *in vitro* selection for anchorage independence selects against anchorage-dependent transformants which grow as I-lines in mice. This means that there are both anchorage-independent and dependent transformants which grow as I-type cells in mice. When the transformants are tested directly in mice, both anchorage-independent and dependent transformants are revealed as I-type. When transformants are first selected for anchorage independence, then analysed in mice, only those which express anchorage independence are revealed. This reduces the total number of cells which express the I phenotype. It follows that if, in addition, there were

anchorage-dependent and independent transformants which were capable of growing as C-lines *in vivo*, the proportion of the I-type relative to the C-type would be the same in these two experiments. As the proportion of I-type varies, it seems that most transformants which express the C phenotype *in vivo* are anchorage-independent and most anchorage-dependent transformants are of the I phenotype.

Because no tumours were anchorage-dependent, any anchorage-dependent transformants must be at a stage on the pathway to cancer that allows the *in vivo* selection of anchorage-independent variants at a high frequency.

Second, the proportion of I- and C-type cells depends on the chemical carcinogen used to transform the N-line. When transformants were selected for anchorage independence before testing in mice, they were induced with various chemical carcinogens. All of the transformants tested directly in mice were induced with BPE. If BPE influences the tumorigenic phenotype of the transformants, then it must induce more I-type transformants than several other carcinogens that were analysed collectively.

The existence of the I phenotype shows that at least some transforming events result in cells which are sensitive to a tumour surveillance mechanism operating in normal but not ATxFL mice. ATxFL mice are severely depressed with respect to both immunological (cell-mediated and humoral immunity) and non-immunological (natural killer (NK) and natural cytotoxic (NC) cells) host protective mechanisms. Although it is possible that one (or both) of these host protective mechanisms is responsible for the destruction of I-lines by normal mice, we cannot ascribe the surveillance measured here to either mechanism. Regardless of the mechanisms of surveillance, the frequency with which transformation by a chemical carcinogen results in the I phenotype is at least three times that of the C phenotype. This is important because the efficacy of any surveillance mechanism is a function of the proportion of newly transformed cells which are susceptible to surveillance.

We acknowledge the contribution of the Armand Hammer Cancer Workshops and the technical assistance of Ms Scotti Brauer. This work was supported by NCI grant CA 19754-07.

A transforming gene present in human sarcoma cell lines

C. J. Marshall, A. Hall & R. A. Weiss

Chester Beatty Laboratories, Institute of Cancer Research, Fulham Road, London SW3 6JB, UK

Morphological transformation of NIH/3T3 cells by transfection with DNA has been used to identify transforming sequences in human tumours^{1,2}. Transforming activity has been reported for DNAs isolated from bladder, mammary, colon and lung carcinomas, neuroblastoma, lymphoid and myeloid tumours¹⁻⁶. Each of these tissues seems to contain different transforming sequences except for the colon and lung tumours where the same sequence seems to be involved⁵. We now report that in two different human sarcoma cell lines, a fibrosarcoma and an embryonal rhabdomyosarcoma, the DNAs have transforming activity. The transforming gene is the same in both sarcomas but differs from the activated sequences detected in other tumours. We have also found that the transforming gene has no detectable homology to eight retrovirus oncogenes tested.

High molecular weight DNA was prepared from three different types of human sarcoma cell lines and assayed for transforming activity on NIH/3T3 cells using the calcium phosphate co-precipitation technique⁷. Table 1 shows that DNA

Fig. 1 Presence of human repetitive sequences in secondary transformants derived from RD and HT1080. DNAs (20 µg) were digested with *EcoRI*, phenol-extracted and loaded on a 1-cm thick, 0.8% agarose gel. After electrophoresis the DNA was transferred to nitrocellulose and the blot was hybridized essentially as described by Wahl *et al.*²⁰ except that the formamide concentration was 30%, the hybridization temperature 60 °C and mouse DNA was used as carrier. The probe used was fetal liver DNA (previously sonicated to an average length of 4 kb) nick-translated to a specific activity of 2×10^8 c.p.m. per µg. The filter was washed in $0.4 \times \text{SSC}/0.1\%$ SDS for 30 min at 60 °C, and subjected to autoradiography with an intensifying screen at -70 °C for 5 days. Lanes a, NIH/3T3; b, c, secondaries derived from HT1080 primary 125; d, e, secondaries derived from HT1080 primary 144; f, g, secondaries derived from HT1080 primary 120; h, i, secondaries derived from RD primary 145; j, secondary from RD primary 149; k, l, secondaries derived from RD primary 148. Arrows show the position of the 8.8 kb band conserved in all transfectants and the 1.8 kb band present in some transfectants. (In lane e of the blot shown the 8.8 kb band is poorly visible, however in other blots of this DNA the band is present though faint.)

from embryonal rhabdomyosarcoma cell line RD (ref. 8) and from one of two fibrosarcomas, HT1080 (ref. 9), was able to transform NIH/3T3 cells. DNA extracted from a second fibrosarcoma cell line, HS10CL7, and from an osteogenic sarcoma, MG63 (ref. 10), as well as normal human DNA did not cause morphological transformation. The transforming efficiencies of RD and HT1080 DNAs were similar, though lower than that of the T24 bladder carcinoma cell line. Individual cells in sarcoma DNA-induced foci were morphologically similar to those produced by the bladder line, but the foci themselves were smaller. This suggests that the transfectants produced using sarcoma DNA grow more slowly than those derived using T24 DNA. The morphologically altered cells were found to initiate rapidly growing tumours with short latent periods (10 days) when injected into nude mice whereas the clone of untransformed 3T3 cells did not produce tumours over a 2-month observation period (Table 1). The transfectants differed from the NIH/3T3 cell line in being able to grow in low-serum and in anchorage-independent conditions. Furthermore, DNA isolated from primary transfectants was able to transform NIH/3T3 cells, demonstrating that the transforming activity could be passaged serially (Table 1).

To determine whether the transforming activity of the human sarcoma cell lines was related to sequences previously identified in other tumour types or to known viral oncogenes the following experiments were performed.

First, DNAs from the sarcoma cell lines, or from primary transfectants, were digested with various restriction endonucleases before transfection of NIH/3T3 cells. Enzymes having sites in the transforming sequence should destroy the transforming activity of the DNA. Digestion of DNA from primary transfectants with six enzymes that cut DNA on average every 3-7 kilobases (kb) completely destroyed the transforming

Table 1 Transfection of NIH/3T3 cells with DNAs from human sarcoma cell lines

Donor DNA	Efficiency of transfection* (no. foci per μg DNA)	Tumorigenicity of transfectants†	Efficiency of secondary transfection*‡ (no. foci per μg DNA)
RD (rhabdomyosarcoma)	0.07 (16/12)	2/2, 2/2 (10 days)	0.14 (11/4), 0.16 (13/4), 0.13 (10/4)
HT1080 (fibrosarcoma)	0.16 (58/18)	3/3, 3/3 (10 days)	0.13 (10/4), 0.28 (22/4), 0.73 (44/3)
HS10C17 (fibrosarcoma)	0 (0/10)	—	—
MG63 (osteogenic sarcoma)	0 (0/12)	—	—
T24 (bladder carcinoma)	1.45 (348/12)	3/3, 3/3 (10–12 days)	6
Normal human DNA from fetal liver	0 (0/12)	—	—
NIH/3T3 cells	0 (0/30)	0/8 (8 weeks)	—

RD, HT1080 and MG63 (refs 8–10 respectively) cells were obtained from the American Type Culture Collection via Flow Laboratories. HS10C17 cells were a gift of Dr G. A. Currie.

* DNA (20 μg) co-precipitated with calcium phosphate was applied to a 60-mm culture dish seeded 24 h previously with 3×10^5 NIH/3T3 clone D4 cells. The medium was changed after 4 h and then every other day and foci were scored after 16–17 days. Values are the mean of several experiments. The number of foci scored/number of plates examined is given in parentheses.

† 10^6 cells from two independent transfectants were suspended in 0.2 ml of medium and injected subcutaneously into two or three 8–12 week old CBA *nu/nu* mice. The mean time for cells to produce 0.5 cm diameter tumours was also recorded. Each value represents the takes from a different independent primary transfectant.

‡ Each set of values represents the transfection efficiencies for a different primary transfectant.

activity (Table 2). Digestion of DNA from a primary transfectant induced by the bladder carcinoma line T24 showed a different sensitivity to digestion, so the sarcoma transforming sequence is not identical to that of the bladder carcinoma¹¹. Similarly, comparison with published data shows that the transforming sequence of the sarcoma DNAs is not the same as that present in mammary³ or lymphocyte⁶ neoplasms. In addition, none of four enzymes (*XhoI*, *Clal*, *SalI* and *SmaI*) having restriction sites that contain the rare dinucleotide CpG and which therefore cut human DNA relatively occasionally inactivated the sarcoma transforming activity. The restriction enzyme sensitivity profiles of RD and HT1080 DNAs are identical for 10 enzymes, suggesting that the transforming activity is associated with the same sequence in both tumours (Table 2).

To characterize the transforming sequence further, we analysed the DNA of secondary transfectants for the presence of human repetitive sequences. After two consecutive rounds of transfection only a small amount of human DNA remains in the transformed cells; any repetitive DNA sequences that are conserved in all secondary transfectants would therefore be expected to be closely linked to or contained in the transforming

Table 2 Effect of restriction endonuclease digestion on the transforming activity of sarcoma DNAs

Enzyme	No. of foci per μg DNA		
	HT1080-f125	RD-f145	T24-f106
No enzyme	0.2	0.28	1.0
<i>EcoRI</i>	0	0	1.0
<i>BamHI</i>	0	0	ND
<i>HindIII</i>	0	0	0.51
<i>BglII</i>	0	0	0.4
<i>PvuII</i>	0	0	0
<i>PstI</i>	0	0	0
<i>XhoI</i>	0.1	0.2	ND
<i>SalI</i>	0.22	0.18	ND
<i>ClaI</i>	0.32	0.18	ND
<i>SmaI</i>	0.13	0.07	ND

DNA (100–200 $\mu\text{g ml}^{-1}$) was digested according to the manufacturers' instructions but using a 10-fold excess of enzyme. After addition of enzyme an aliquot containing 1 μg of DNA was removed and added to 1 μg of λ DNA. Complete digestion of λ DNA was taken to correspond to complete digestion of cellular DNA. 60 μg of digested DNA were added to 120 μg of high molecular weight mouse DNA and calcium phosphate co-precipitates were divided between six plates of NIH/3T3 cells. For all cell lines, DNAs of primary transfectants were used for restriction digests because their transforming activity was higher than that of the original cell lines. In confirmatory experiments, digests of DNA from the original human cell lines gave similar results.

Fig. 2 Southern blots of *EcoRI* (A–C) or *BamHI* (D) digestions of the following DNAs: a, human fetal liver; b, NIH/3T3; c, a primary HT1080 transfectant; and d, a primary RD transfectant. The blots were hybridized with the following ^{32}P -labelled viral oncogene probes: A, a 1.5 kb *PstI* fragment containing *v-myc*; B, a 2.5 kb *PvuII* fragment containing *v-erb-A* and *v-erb-B*; C, a 1.8 kb *PvuII* fragment containing *v-Ki-ras* and flanking sequences (the arrow indicates the position of the human 3 kb *EcoRI* fragment homologous to the viral oncogene and identified in NIH/3T3 cells transfected with human lung carcinoma DNA¹⁶); D, a 0.9 kb *PstI/XbaI* fragment containing *v-sis*. All four blots were hybridized in 50% formamide, $5 \times \text{SSC}$ at 42°C except D which was at 50°C . The filters were washed as follows: A, $0.3 \times \text{SSC}$, 65°C ; B, $0.1 \times \text{SSC}$, 45°C ; C, $0.3 \times \text{SSC}$, 60°C ; and D, $0.6 \times \text{SSC}$, 50°C .

sequence^{4,5}. A Southern blot¹² profile of such conserved repetitive sequences can be used to distinguish different transforming sequences^{4,5}. Accordingly, DNAs were isolated from secondary transfectants derived from RD and HT1080 DNAs, digested with *EcoRI* and probed on Southern blots with nick-translated total human DNA¹³. In the conditions of hybridization used, only human repetitive sequences can be detected. Although several fragments are present in each transfectant, only a single 8.8 kilobase pair (kbp) *EcoRI* fragment is conserved in all secondary transfectants (Fig. 1). Identical Southern blots probed with the plasmid BLUR-8 (ref. 14), which contains a cloned repetitive sequence from the human *Alu* family, show a similar pattern of hybridization (data not shown). However, the band corresponding to the 8.8 kbp *EcoRI* fragment is less intense than the other bands. We assume that the repetitive sequence present in this fragment is only distantly related to the *Alu* repetitive element contained in BLUR-8. Many of the secondary transfectants also contain a second fragment of 1.8 kbp (Fig. 1). However, as this fragment is not conserved in all secondary transfectants, it is probably not contained in the transforming sequence but may be linked to it. The observation that an 8.8 kbp *EcoRI* fragment is conserved in all secondary transfectants derived from both RD and HT1080 DNAs again strongly suggests that the transforming sequence in the two

DNAs is the same. Furthermore, the size of the *EcoRI* fragment is different from the fragments found by other investigators in secondary transfectants from DNAs of colon, lung, neuroblastoma and promyelocytic leukaemia^{4,5}.

Recently it has been shown that the transforming sequence activated in bladder carcinoma cell lines is a human cellular homologue of *v-Ha-ras*, the oncogene of Harvey sarcoma virus¹⁵. The transforming sequence of a lung carcinoma cell line is homologous to *v-Ki-ras*, the oncogene of Kirsten sarcoma virus¹⁶. Furthermore, Eva *et al.*¹⁷ have reported that human sarcoma cells contain high levels of RNA transcribed from the cellular homologue of *v-sis*, the oncogene of simian sarcoma virus. It was therefore important to determine whether the sarcoma transforming sequence is related to these or other retrovirus oncogenes. We have probed Southern blots of transfectants to see whether they contain human sequences homologous to *v-erb-A*, *v-erb-B*, *v-Ki-ras*, *v-myc*, *v-sis* (Fig. 2) and to *v-abl*, *v-Ha-ras* and *v-src* (data not shown). None of these probes detected any human sequences in the transfectants although the conditions used detected the mouse homologues

in the transfectants and the human homologues in human DNA.

We conclude from these experiments that the same transforming sequence is present in cell lines derived from the two different types of sarcoma, a rhabdomyosarcoma and a fibrosarcoma. (Recently other workers¹⁸ noted that HT1080 DNA has transforming activity.) We have shown that this sarcoma sequence is different from transforming sequences identified in other human tumour lines and in eight RNA tumour viruses. These data therefore support the idea that different transforming sequences are activated in different tumour types and that these sequences may have a role in both the normal physiology and the neoplastic transformation of those tissues^{3-6,19}. Further characterization of the transforming sequence and the elucidation of its mode of action will depend on the isolation of molecular clones of the transforming gene and its normal allele.

We thank James Christie and Micaela Fairman for technical assistance, R. Avery, J. M. Bishop, R. C. Gallo, J. Neil and B. Ozanne for cloned retrovirus oncogenes and C. Schmid for the BLUR-8 clone. Financial support was generously provided by the Cancer Research Campaign and MRC.

The production of membrane or secretory forms of immunoglobulins is regulated by C-gene-specific signals

Luciana Forni & Antonio Coutinho*

Basel Institute for Immunology, 487 Grenzacherstrasse, Postfach, 4005 Basel, Switzerland

* Department of Immunology, Umeå University, 90185 Umeå, Sweden

Selective patterns of antibody isotypes are produced in response to thymus-dependent and thymus-independent antigens and mitogens¹⁻⁵. Together with information on the organization of immunoglobulin C_H genes in myelomas^{6,7}, various models on the control of C-gene expression and switch in normal B cells have been proposed but only secreted products or secretory cells have been considered. We report here a dissociation between expression of membrane-bound immunoglobulins and secretion of the same isotype, and in this case describe C-gene specific signals which regulate the production of membrane versus secretory forms of immunoglobulin. These results indicate that regulation of isotypic patterns operate at levels other than immunoglobulin gene structure, and suggest that the secretory phenotype alone is inadequate as the measure of C-gene expression.

Spleen cells were exposed to either the T-independent mitogen lipopolysaccharide (LPS)⁸ or helper T cells which specifically activate a large set of B cells⁹. Activation of B cells under these two conditions results in two distinct patterns of γ -isotype secretion although activation of μ secretion is comparable in both cases. T-independent induction results in pre-dominant secretion of $\gamma 2b$ and $\gamma 3$, while helper cells induce primarily $\gamma 1$ and $\gamma 2a$, but here we have also studied the expression of membrane-bound immunoglobulins. As shown in Table 1, following T-independent induction, $\gamma 1$ is the pre-dominant membrane isotype, indicating a clear discrepancy between the expression and the secretion of this particular

isotype. The dissociation between expression of membrane and secretory form of $\gamma 1$ cannot be explained by different kinetics, as high frequencies of $\gamma 1$ -bearing blasts are observed from days 3 to 7 of culture. Passive adsorption of $\gamma 1$ on LPS blasts is unlikely because the concentration of this isotype in culture supernatants remains low (A.C. and L.F., in preparation), and therefore would require the presence of Fc receptors with exquisite specificity and high affinity for $\gamma 1$, which is not the case for B lymphocytes¹⁰. In contrast, no dissociation of membrane and secretory isotypes was observed after exposure to T helper cells.

We addressed the question of the fate of such LPS-induced, $\gamma 1$ -bearing cells, and of the mechanisms responsible for the dissociation between expression and secretion observed in LPS cultures. We attempted to correct the secretory defect of LPS-activated populations by exposure to specific T-cell help. LPS-activated blasts re-exposed to either LPS or to helper cells produce 3 days later quite distinct isotypes (Table 2). The T-dependent re-stimulation resulted in: the appearance of a high number of $\gamma 1$ secretors which are missing in LPS culture (the number of these is very close to the one of $\gamma 1$ -bearing cells in the starting population); decrease of $\gamma 3$ and $\gamma 2b$ secretors (although at values still higher than in helper cultures) and a significant increase of α plaque-forming cells (PFC). Note that in both cases a comparably high fraction (40%) of all recovered cells are high rate secretors and, of these, a similar proportion (57% and 56%) secrete γ ; both stimuli seem therefore to be equally competent in inducing switch and terminal maturation. The differences are isotype specific and relate to the quality of the stimulus controlling terminal maturation in the same population of activated cells.

To define further the specificity of the maturation signals, we analysed similar cultures both for cells expressing membrane-bound immunoglobulins and PFC. Table 3a shows that LPS is fully competent to induce $\gamma 3$ secretion, and ineffective with regards to $\gamma 1$ secretion. On the other hand, helper activity does induce $\gamma 1$ secretion. As, however, it also doubles the number of $\gamma 1$ -bearing blasts, LPS-activated, $\gamma 1$ -bearing blasts may remain nonsecretory in the presence of helper cells, which

Table 1 Isotype distribution of secreted and membrane-bound immunoglobulin molecules

C _H isotype	Isotype distribution (%) [*]			
	Cultures stimulated with LPS		Cultures stimulated with specific helper T cells	
	Secreted [†]	Membrane bound [‡]	Secreted [†]	Membrane bound [‡]

γ1	3.3	35.4	66.0	67.2
γ2b	51.1	27.0	4.6	9.1
γ2a	8.1	14.7	19.0	16.2
α	1.3	1.7	7.4	7.1

Normal spleen cells from C3H/Tif mice were cultured in RPMI medium supplemented with 5×10^{-5} M 2-mercaptoethanol, 10 mM glutamine, 10 mM HEPES, antibiotics and 20% fetal calf serum (Gibco) (5×10^5 ml⁻¹, 2 ml⁻¹ per culture). The cultures were stimulated with either $50 \mu\text{g ml}^{-1}$ lipopolysaccharide from *Salmonella abortus equi* (Difco) or 2×10^5 helper cells from C3H/HeJ anti-C3H/Tif cell lines that were established and maintained in continuous growth *in vitro* over the last 16 months by weekly stimulation with irradiated C3H/Tif spleen cells, according to methods previously described in detail¹⁹. The helper cells used in these experiments were from clones isolated by limiting dilution in suspension cultures which activate C3H/Tif spleen cells as described, but are MHC-restricted (unpublished), in contrast to uncloned lines reported before in this strain combination^{19,20}. The 'effector helper to target spleen cell' ratios used here (1:5) had previously been found optimal in these conditions.

^{*} The values are expressed as percentages of the total numbers of cells expressing the isotypes listed in the table. These are mean values of two independent experiments.

[†] Assays for secreting cells were performed after 6–7 days of culture when non-IgM PFC accounted for 50–60% of all PFC, representing 20–25% of all viable cells. Plaque-forming cells (PFC) were detected in a Protein A plaque assay using isotype-specific rabbit antisera^{21,22} raised by injection of purified myeloma proteins of the different isotypes.

[‡] Assays for membrane-bound isotypes were performed at days 3–4 of culture. Cells bearing membrane isotypes other than μ accounted for 25–30% of all cells. When tested in double staining with anti- μ , most cells were found also to bear IgM in conjunction with another C_H isotype. Rabbit antisera raised against purified myeloma proteins were made specific by adsorption of Sepharose-coupled myeloma proteins of different isotypes, as well as F(ab')₂ fragment prepared by pepsin digestion of total IgG from pooled mouse sera. The specificity of the antisera was assayed in solid-phase enzyme immunoassay²³. Conjugation with fluorochromes as well as staining for membrane-bound immunoglobulins was performed as described²⁴.

independently induce γ3-bearing cells to switch to γ1 expression and secretion, thus accounting for the disappearance of γ3 producers on the whole. To distinguish between the two possibilities we examined single cells for the presence of membrane-bound and intracytoplasmic immunoglobulins by double immunofluorescence. This was done soon after restimulation because with the half lives of message and proteins, it should be possible to determine the isotype persisting on the membrane of cells that were newly activated to secretion. Table 3b shows that about half of the γ1-bearing blasts, which in this short period had not greatly increased in number, had been activated to produce intracytoplasmic γ1 by helper cells. This resulted in a proportion of secretors, out of the total γ1 population, which is one order of magnitude higher than in parallel LPS

cultures. The switch from γ3 to γ1, measured as cells with intracytoplasmic γ1 and membrane γ3, was proportionally more frequent in LPS than in helper cell-stimulated cultures. On the other hand, the decay of γ3 cells, both membrane-positive and secretors, was observed after 20 h of restimulation. As the proportion of secretors out of the total γ3 population remains unaffected, the decay of γ3-producing cells can only be explained by inability of helper cell signals, in contrast to LPS, to maintain proliferation and/or viability of γ3-bearing cells and to activate them to secretion. Preliminary experiments indicate that comparable results can be obtained with supernatants of the T-cell clones used in these experiments, which suggests that neither of the T-cell effects, induction of γ1 secretion and inability to support γ3 production, requires cell-to-cell contact.

To confirm that γ1 secretors in helper cell-restimulated cultures derive from γ1-bearing blasts present in LPS cultures, positive selection in a fluorescence-activated cell sorter (FACS II) was carried out. As shown in Table 4, a large number of γ1 high-rate secretors were induced within 15 h by T helper cells in the γ1-enriched but not in the γ1-depleted population, indicating that few, if any γ1 PFC are newly derived from either μ or γ3 to γ1 switches. As the majority of the γ1-bearing blasts in LPS cultures switched from μ (and δ) production after mitogen stimulation (only 2% or less of spleen cells are γ1 positive) we conclude that thymus-independent B-cell activation can induce switches to γ1 expression but is very inefficient in activating γ1 secretion. This operates in a strict C-gene specific manner, because the mitogen is fully competent to induce secretion not only of γ3, but also of γ2b and γ2a, which are coded by genes located distally from γ1. Table 4 also shows that helper cells are much less efficient than LPS in inducing γ3 secretion in the γ1-depleted population and this, in view of the short subculture period, is unlikely to be the result of preferential survival or expansion of γ3 cells in LPS cultures.

The present observations show that measurements of antibodies and secreting cells is insufficient when considering C-gene expression. They also point out that isotype commitment in antibody responses^{1–3} is regulated at levels other than DNA rearrangements and gene structure. In the example described here, the regulation of membrane-versus-secretory forms of immunoglobulins is intimately connected to the control of terminal maturation to high-rate secretion and dependent on the quality of the activating signal. It has been known for some time that the carboxy terminus of membrane μ is encoded in a separate exon, distinct from the C μ 4 domain¹¹, and it is now established that all other C_H genes exhibit the same type of structure^{12–14}. Models based on differential nuclear RNA splicing and/or selective termination of transcription, as well as post-translational controls, have been proposed to explain the production of membrane-bound or secretory heavy chains. The physiological mechanisms regulating these processes are unknown, but the present experiments prove the existence of

Table 2 Differential effects of LPS and helper T cells on secretion of γ isotypes

	PFC per 10 ⁵ B cells [*]						Total PFC	Total non-IgM PFC

C3H/Tif spleen cell cultures were stimulated with LPS and assayed after 3 days of culture for the presence of membrane-bound immunoglobulins by immunofluorescence and of plaque-forming cells of different C_H isotypes (see Table 1 legend). Such 3-day LPS blasts were then subcultured in Microtitre II plates (Falcon) at 2×10^4 cells in 0.2-ml cultures in the same medium with either LPS ($50 \mu\text{g ml}^{-1}$) or with C3H/HeJ anti-C3H/Tif helper cells (4×10^3 per culture) and isotype-specific PFC were determined after an additional 3 days of culture.

^{*} The values are expressed per 10⁵ initial cells, and per 10⁵ recovered cells, to facilitate the comparison between the results obtained with the different assays. The total number of B cells recovered per culture was very similar after exposure to LPS or to T helper cells (1.8 ± 0.2 and $1.65 \pm 0.18 \times 10^5$ respectively).

[†] Figures in parentheses represent the number of cells in the starting population positive on the membrane by immunofluorescence. ND, not determined.

Table 3 Effect of LPS and T helpers on expression and secretion of $\gamma 3$ and $\gamma 1$

a	LPS day 3	% Blasts in culture		3 days LPS +3 days TH
		3 days LPS	3 days LPS

Proportion of secretors out of the total membrane-positive population						
$\gamma 3$	—	0.51	0.51	0.75	—	—
$\gamma 1$	—	0.035	0.042	0.53	—	0.73

Day 3 LPS blasts subcultured with either LPS or T helper cells (TH) and assayed in the conditions described in the legends to Tables 1 and 2. *a*, 3 days subculture. Separate samples of the same cultures were stained by immunofluorescence for membrane-bound immunoglobulins, or assayed for $\gamma 3$ and $\gamma 1$ PFC. *b*, 20 h subculture. The same cell samples were stained by double immunofluorescence for membrane-bound and intracytoplasmic $\gamma 3$ and $\gamma 1$ (ref. 24). ND, not determined.

Table 4 Early effects (15 h subculture) of LPS and T helper cells on secretion of $\gamma 3$ and $\gamma 1$ by selected membrane $\gamma 1^+$ and $\gamma 1^-$ LPS blasts

Cell population	Isotype of PFC	PFC per 10^5 recovered cells Mitogen in subculture		
		None	LPS	T helper cells
Membrane $\gamma 1^+$	$\gamma 1$	915	900	6,450
LPS blasts	$\gamma 3$	375	550	300
Membrane $\gamma 1^-$	$\gamma 1$	<15	<15	300
LPS blasts	$\gamma 3$	650	9,150	2,750

Day 3 LPS-activated blasts were stained with fluorescein-labelled anti- $\gamma 1$ and separated in the fluorescence-activated cell sorter (Becton and Dickinson FACS II). The $\gamma 1^+$ and $\gamma 1^-$ populations represent the 10% brightest and 10% dimmest cells, respectively. Conditions of primary and secondary cultures and assays were as described in the legends to Tables 1 and 2.

such controls and demonstrate that they are C-gene specific.

Our results stress that such C-gene specificity concerns terminal maturation (high rate production of secretory form), and not switch, as implied before¹⁻⁵ and might operate independently of whether the cell has undergone¹⁵⁻¹⁷ a switch recombination or not¹⁸. Whatever the precise mechanism involved here, it is clear and quite astonishing that the ability to produce the secretory form of immunoglobulins is related to the quality of the activating signal in a C-gene specific manner. As we have studied polyclonal B-cell responses that proceed independently of immunoglobulin (V-region) specificity, it is likely that such C-gene specific regulation is mediated by cellular structures other than immunoglobulin receptors.

The Basel Institute for Immunology was founded and is supported by Hoffmann-La Roche, Basel. This work was partly supported by the Swedish MRC. We thank Ms M. Tuneskog for technical help, Ms W. Breisinger and Ms M. Bühler for typing the manuscript, all participants in the Second Umeå Seminar on Immunobiology for discussion, and Chris Paige for critical reading of the manuscript.

An adenovirus glycoprotein binds heavy chains of class I transplantation antigens from man and mouse

Christer Signäs, Michael G. Katze*, Håkan Persson* & Lennart Philipson*

Department of Microbiology, University of Uppsala, The Biomedical Center, Box 581, S-751 23 Uppsala, Sweden

The successful killing of virus-infected cells by cytotoxic T lymphocytes (CTL) is dependent on the recognition of both a viral product and class I antigens of the major histocompatibility complex (MHC) on the infected cell surface¹⁻⁹. Whether these two entities are found independently on the cell surface and therefore recognized by two different CTL receptors, or whether they are associated together and can therefore be recognized by a single receptor is not known¹⁰. The association between an adenovirus-encoded glycoprotein expressed on the cell surface early after infection and class I antigens has been investigated and it has been found that antisera against class I antigens can co-precipitate the antigen and the viral glycoprotein from an adenovirus-transformed cell line from the Hooded-Lister rat strain^{11,12}. We show here by *in vitro* affinity chromatography and *in vivo* immunoprecipitation that the viral glycoprotein specifically binds to the heavy chain of class I antigens in both man and mouse.

An adenovirus glycoprotein E3/19K (ref. 13), encoded in region 3 of the adenovirus genome, is found soon after infection. When the glycoprotein fraction from cytoplasmic extracts of infected HeLa cells or a human adenovirus-transformed epithelial cell line (293)¹⁴ superinfected with adenovirus type 2 (Ad2) was immunoprecipitated with anti-HLA antisera both the E3/19K and the heavy chain of the HLA were immunoprecipitated in infected but not in uninfected cells (Fig. 1). From counting the radioactivity in the bands it appears that the two moieties are present in almost equimolar amounts and that most of the HLA chains are bound to E3/19K (not shown). However, in productive infection with Ad2 the E3/19K is overproduced and only around 5-10% of the viral glycoprotein

*Present addresses: Molecular Biology and Genetics, Unit of the Graduate School, Memorial Sloan-Kettering Cancer Center, New York, New York 10021, USA (M.G.K.); Laboratory of Molecular Genetics, National Institute of Child Health, and Human Development, Bethesda, Maryland 20205, USA (H.P.); European Molecular Biology Laboratory, Postfach 10-2209, D-6900 Heidelberg, FRG (L.P.).

is associated with the class I antigens but in transformed rat cells more than 80% of the viral E3/19K is associated with the class I antigen¹¹. Control experiments showed that artificial mixtures of purified E3/19K and cells did not result in co-precipitation of the complex. The E3/19K protein can thus bind strongly to human transplantation antigen *in vivo* as previously demonstrated for the class I antigen of rats^{11,12}. Given these results we analysed whether this complex could also be formed *in vitro*. Purified E3/19K (Fig. 2h) was coupled to CNBr Sepharose 4B. The glycoprotein fraction from ³⁵S-methionine-labelled cytoplasmic extracts from two human established lymphoid cell lines (Ingemar B7 and IM-199), which express mainly the class I antigens B7 and A2, were passed over the column. A column prepared with coupled bovine serum albumin (BSA) was the control. Figure 2 shows that a polypeptide of the same molecular weight as the heavy chain of the HLA-B7 allotype specifically bound to the E3/19K column but not to the BSA column. This polypeptide represents the heavy chain of the HLA as revealed by immunoprecipitation (Fig. 2e). It can also be seen that the amount of this polypeptide

Fig. 1 Immunoprecipitation from uninfected and adenovirus-infected HeLa and 293 cells with anti-HLA serum. Suspension cultures of HeLa cells were labelled overnight with ³⁵S-methionine (10 μ Ci ml⁻¹) to enhance labelling of the class I MHC antigens, in methionine-free spinner medium (M) supplemented with 2.5% normal medium and 7% calf serum. Monolayers of 293 cells were labelled similarly using Eagle's medium and 10% fetal calf serum. The cells were washed twice and infected with adenovirus type 2 (ref. 18). Cycloheximide (25 μ g ml⁻¹) was added 2 h post-infection and removed 3 h later in order to enhance early viral mRNA accumulation¹⁹. The cells were then labelled for an additional 3 h with ³⁵S-methionine (10 μ Ci ml⁻¹) in the presence of cytosine arabinoside (25 μ g ml⁻¹). The cells were washed in phosphate-buffered saline (PBS) and lysed in 0.5% NP40, 150 mM KCl, 1.5 mM MgCl₂, 10 mM Tris-HCl pH 8.0. The cytoplasmic extracts (2 ml from 2×10^8 cells) were passed over a lentil lectin Sepharose column (4 ml) (Pharmacia) equilibrated with PBS, 0.1% Triton X-100, 1 mM phenylmethylsulfonyl fluoride (PMSF) (buffer A). Elution was performed with buffer A containing 0.1 M α -methylmannoside. The glycoprotein eluate was immunoprecipitated after preprecipitation with an unrelated immune complex and analysed on 13% SDS-polyacrylamide gels²⁰. The anti-HLA serum used was a mixture of a monoclonal antiserum that recognizes HLA-A, -B or -C antigens²¹ and a rabbit antiserum made against papain-solubilized HLA. Lanes a, d, immunoprecipitation with normal rabbit serum; b, c, e and f, immunoprecipitation with anti-HLA serum. a, c, infected HeLa cells; b, uninfected HeLa cells. d, f, infected 293 cells; e, uninfected 293-cells. In this and subsequent figures ³⁵S-labelled adenovirus proteins were used as size markers M.

Fig. 2 Affinity chromatography of human class I antigens on the adenovirus glycoprotein. The adenovirus E3/19K protein (100 μ g) or bovine serum albumin (100 μ g) was coupled to 1 ml cyanogen bromide-activated Sepharose 4B (Pharmacia). Two different lymphoid cell lines, HLA-A2 and HLA-B7, were labelled overnight with ³⁵S-methionine (10 μ Ci ml⁻¹), cytoplasmic extracts were prepared, and the glycoproteins isolated by lentil lectin chromatography as described in Fig. 1 legend except that 2 mM dithiothreitol (DTT) was included in the buffers. The lentil lectin eluate was dialysed against buffer A (see Fig. 1), divided in two aliquots and passed over the BSA and the E3/19K columns respectively at 4 °C. The columns were washed thoroughly and eluted with buffer A containing 2 M NaCl and 2 mM DTT. Each fraction was analysed by SDS-polyacrylamide gel electrophoresis and immunoprecipitated as described in Fig. 1 legend. a, Percolate of HLA-B7 from the BSA column; b, percolate of HLA-B7 from the E3/19K column; c, eluate BSA column; d, eluate E3/19K column; e, eluate from E3/19K column immunoprecipitated with anti-HLA serum. No precipitate was observed with normal serum. f, g Show the percolate and eluate fractions of HLA-A2 glycoproteins; h, purified E3/19K. The size marker M is described in Fig. 1 legend.

is decreased in the eluate of the E3/19K column compared with the BSA column. The same results were obtained with the HLA-A2 cells (Fig. 2f, g). These results suggest that the E3/19K can specifically bind to different allotypes of the class I transplantation antigens of man.

We also examined *in vitro* binding of mouse class I antigens using the cell line YAC1 (H-2^a derived from a H-2^k/H-2^d hybrid). Figure 3 shows that a polypeptide of a similar size to that from humans specifically bound to the E3/19K column. Immunoprecipitation with anti-H-2-serum established that this polypeptide corresponded to the heavy chain of the H-2 antigen (not shown). It appears therefore, that the binding of E3/19K to the heavy chain class I transplantation antigens does not show species specificity.

To localize the site of interaction between the two molecules we attempted to perform enzymatic digestions of plasma membranes in order to release the complex. The heavy chain of the class I antigens can be released from membranes with papain, creating the 32,000 (32K) and 34,000 (34K) molecular weight (M_r) subspecies¹⁵. However, papain treatment of infected HeLa cells could not release a complex containing both moieties when analysed by immunoprecipitation with anti-HLA serum. Instead the viral glycoprotein remains in the plasma membrane pellet together with uncleaved or partially cleaved antigen (Fig. 4). The use of an affinity chromatography column with papain released fragments of the human HLA-B7 antigen confirmed this. Figure 4b demonstrates that very few papain fragments are bound to the E3/19K column even though the columns were loaded with material carrying eight times more radioactivity than in the previous experiments. These results suggest that the major interaction occurs either close to the cell membrane or on the cytoplasmic side of the membrane but a

configurational change in the papain fragments cannot be excluded. It is also possible that nonspecific hydrophobic interactions occur between the proteins where they penetrate the membrane, but we consider this unlikely as Triton X-100 was used in all the buffers and a nonspecific interaction may not give the selectivity observed.

If a cytoplasmic interaction guides the complex formation, considerable variation in this region of the transplantation antigens could account for the diversity in CTL recognition. Recent analyses of the genomic structure of the HLA and H-2 genes indeed suggest that the cytoplasmic portions of the class I transplantation antigens are complex and contain at least three exons with varying splice patterns for the H-2 genes^{16,17}.

The strong complex formation between adenovirus glycoprotein and the transplantation antigens appears to be unique among the viral systems investigated so far. The influenza virus haemagglutinin⁹, the vesicular stomatitis virus glycoprotein⁵ and several other identified virus determinants for the T-cell mediated cytotoxicity⁵⁻⁹ do not appear to be co-precipitated with the heavy chain of the class I antigens. The adenovirus system, including the mouse adenovirus, where an S-antigen is firmly complexed to the class I transplantation antigens of the mouse⁸, may therefore be a model for the altered self hypothesis of virus-induced T-cell cytotoxicity. We have previously demonstrated that this complex in rat cells is recognized by syngeneic rat cytotoxic T cells and that this reaction can be inhibited by syngeneic antibodies to the cells and allogeneic

Fig. 3 Affinity chromatography of mouse class I antigens on the adenovirus glycoprotein. A labelled cytoplasmic extract from the YAC (H-2^{kd}) cells was treated exactly as in Fig. 2. *a*, Percolate from the E3/19K column; *b*, eluate. The size marker M is described in Fig. 1 legend.

Fig. 4 Immunoprecipitation of papain-treated membranes from infected and mock-infected HeLa cells (*a*) and affinity chromatography of papain-released HLA-B7 on the E3/19K column (*b*). HeLa cells were labelled and infected as described in Fig. 1 legend. The cells were collected by centrifugation and membrane preparation and papain treatment was performed as previously described²². The supernatant after papain digestion was dialysed against PBS, 1% Triton X-100, 1 mM PMSF and immunoprecipitated. The pellet was dissolved in PBS, 1% Triton X-100, 1 mM PMSF by stirring overnight at 4 °C. The dissolved pellet was also immunoprecipitated and the samples were analysed by SDS-gel electrophoresis. HLA-B7 cells were labelled as described in Fig. 1 legend. Membrane preparation and papain treatment was performed as described above. The supernatant after papain treatment was dialysed against PBS, 0.1% Triton X-100, 1 mM PMSF and added to the E3/19K column was described in Fig. 2 legend. *A*, Immunoprecipitation with anti-HLA serum from the supernatant (*s*) and pellet (*p*) after papain digestion of HeLa cells; *a*, uninfected; *b*, infected cells. *B*, Affinity chromatography on E3/19K protein column. Lane *a*, percolate, and lane *b*, high salt eluted fraction. The size marker M is described in Fig. 1 legend.

antibodies to the class I transplantation antigen¹². By using the complexes, which are retained on the affinity columns, as immunogen for the production *in vivo* of both specific antibodies and cytotoxic T cells, we hope to be able to define the T-cell receptor and the role of the CTL in virus infection.

We thank B. M. Johansson for technical assistance and Marianne Gustafson for secretarial help. The HLA and H-2 antisera were provided by Drs W. Bodmer and P. Peterson. We also thank Dr J. Andersson, for the YAC-1 cell line and critical comments. M.G.K. was supported by a postdoctoral fellowship from the EMBO. This work was supported by grants from the Swedish MRC and the Swedish Society against Cancer.

Molecular cloning of the gene for human anti-haemophilic factor IX

K. H. Choo, K. G. Gould, D. J. G. Rees & G. G. Brownlee

Sir William Dunn School of Pathology, University of Oxford, South Parks Road, Oxford OX1 3RE, UK

A functional deficiency of factor IX, one of the coagulation factors involved in blood clotting¹, leads to the bleeding disorder known as Christmas disease², or haemophilia B. Both this disease and haemophilia A (factor VIII (C) deficiency) are X chromosome-linked and together occur at a frequency of ~1 in 10,000 males. The molecular basis for the functional alteration of factor IX in Christmas disease is not clearly understood. As a first step towards the elucidation of the molecular events involved, we have attempted molecular cloning of the factor IX gene. We used a bovine factor IX cDNA clone, isolated using synthetic oligonucleotides as probes, to screen a cloned human gene library. Here we report the isolation and partial characterization of a λ recombinant phage containing the human factor IX gene.

As a first step in the isolation of a cDNA clone for bovine factor IX, bovine liver was used to prepare total mRNA by the guanidine hydrochloride method³. A preparation enriched in factor IX-specific mRNA was obtained by oligo (dT)-cellulose chromatography, followed by two successive separations by sucrose gradient centrifugation. The enrichment was monitored by a specific immunological assay based on cell-free translation using rabbit reticulocyte lysates (Fig. 1). A sucrose gradient fraction sedimenting at 20–22S was found to be enriched (about 10-fold) for the bovine factor IX mRNA, and was therefore used in the following cloning experiments.

Synthetic oligonucleotides were used⁴ to produce a cloned cDNA library. From the available amino acid sequence data for bovine factor IX⁵, two different sets of oligonucleotides were synthesized. The first set [designated oligo (N-1)] was deduced from the amino acid sequence residues 348–352 (His-Met-Phe-Cys-Ala) and was synthesized, using the solid phase phosphotriester method⁶, as a mixture of eight different sequences (5'-GC₆CA₆AACAT₆TC-3'). The second set of oligonucleotides [oligo (N-2)] was deduced from amino acids 70–75 (Glu-Cys-Trp-Cys-Gln-Ala); this was synthesized as two mixtures of eight different sequences each (5'-GCTTG₆CACCA₆CA₆TC-3' and 5'-GCCTG₆CACCA₆CA₆TC-3').

From a knowledge of the concentration of factor IX in blood plasma (~2–4 $\mu\text{g ml}^{-1}$) and of the amount of ³⁵S-cysteine counts precipitable by anti-factor IX antibodies, the abundance of factor IX mRNA was estimated to be as low as 0.01%. Therefore, to achieve further enrichment for factor IX mRNA, oligo (N-1) was used as a primer to synthesize cDNA from the sucrose gradient-enriched poly(A)-mRNA preparation. A library of 7,000 colonies was prepared and screened using ³²P-labelled oligo (N-2) (see Fig. 2 legend). One colony (designated BIX-1) gave a positive hybridization signal above background. Characterization of this colony by restriction endonuclease cleavage

(data not shown) indicated that it contained a DNA insert of ~430 base pairs (bp). Figure 2 shows part of the nucleotide sequence, that is, 304 residues of the BIX-1 insert, and confirms that it is a bovine factor IX sequence. It is interesting that only part of the insert sequence (amino acid residues 52–139) corresponds directly to the nucleotide sequence predicted from the known bovine amino acid sequence data⁵. Over this region, there are no discrepancies between BIX-1 and the published data for factor IX, except at nucleotides 38–40 which code for Asp instead of Thr. This amino acid change was also observed in a second, independent cDNA clone. (This latter clone, which

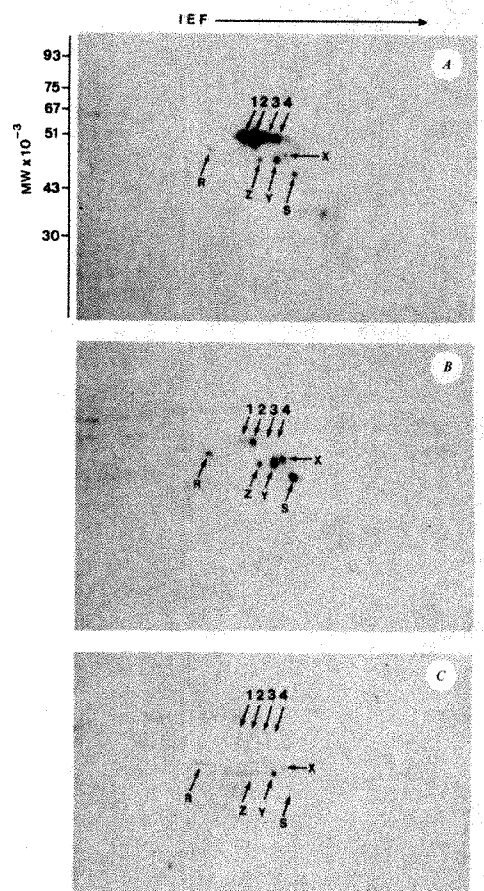

Fig. 1 Two-dimensional polyacrylamide gel electrophoretic analysis of immunoprecipitated cell-free translation products of bovine liver mRNA. mRNA purified through an oligo (dT)-cellulose column¹¹ was translated in a rabbit reticulocyte cell free system¹² in the presence of ³⁵S-cysteine. After incubation at 29°C for 90 min, samples were treated for immunoprecipitation as described previously¹³. Crude antiserum against pure bovine factor IX was raised in rabbit. Specific anti-factor IX immunoglobulins used for immunoprecipitation were purified as described previously¹⁴ by passage of the crude antiserum through a Sepharose 4B column to which pure bovine factor IX had been coupled. After incubation, the antibody-antigen complex was precipitated by the addition of protein A-Sepharose CL-4B resin (Pharmacia), washed and resolved on a two-dimensional polyacrylamide gel¹⁵. A, immunoprecipitation was performed in the presence of purified antibodies; B, same as for A, except that immunoprecipitation was performed in the presence of both antibodies and a competing amount of unlabelled pure bovine factor IX; C, same as for A, except that immunoprecipitation was performed in the presence of a control antiserum from a rabbit which had not been immunized with factor IX. 1–4, Factor IX polypeptide spots; evidence for this comes from the fact that (1) these are the predominant spots immunoprecipitated by the specific antibody; (2) their molecular weight (~50,000, a single polypeptide chain plus a possible pre-peptide signal sequence) is compatible with published data⁵; (3) the spots are specifically competed for by pure factor IX; and (4) they are absent from the gel when control serum is used. (Partial chymotryptic digestion of polypeptide spots 1 and 2 (data not shown) suggests that they are related and may have arisen as a result of post-translational modification; the amount of material recovered from spots 3 and 4 was insufficient for these to be compared.) R, S, X, Y, and Z designate nonspecific background polypeptide spots which form useful reference points on the two-dimensional gel. The molecular weights (MWs) of the polypeptide markers on the second dimension gel are shown on the left. IEF designates isoelectric focusing in the first dimension¹³, SDS, polyacrylamide gel electrophoresis in the second dimension¹³.

Fig. 2 Isolation and characterization of bovine BIX-1 clone. A library of clones containing bovine cDNA inserts was prepared as follows. First, cDNA strands were synthesized as described elsewhere¹⁵ except that 2 μ g of oligo (N-1), 20–30 μ g of sucrose gradient-enriched poly (A)⁺ mRNA, 10 μ Ci [α -³²P]dATP (3,000 Ci mmol⁻¹; Amersham) and 50 U of reverse transcriptase were used in a 50 μ l reaction mixture. The cDNA was phenol-extracted, desalted on a Sephadex-G100 column, then treated with alkali (0.1M NaOH, 1mM EDTA) at 60 °C for 30 min to remove the mRNA strand. Second strand DNA was synthesized as described elsewhere¹⁵. The double-stranded DNA was then cleaved with the restriction enzyme *Mbo*I and ligated to pBR322 which had been cut with *Bam*HI and treated with calf intestinal alkaline phosphatase to minimize vector self-religation. The ligated DNA was used to transform *Escherichia coli* strain MC1061 (ref. 16). A library of 7,000 ampicillin-resistant colonies was obtained. Of these, ~85% were tetracycline-sensitive. The library of colonies were transferred in an unordered fashion to 13 Whatman 541 filter papers, amplified with chloramphenicol, and prepared for hybridization as described by Gergen *et al.*¹⁷. The filters were prehybridized at 65 °C for 4 h in 6 \times NET, 5 \times Denhardt's, 0.5% NP-40 and 1 μ g ml⁻¹ yeast RNA described by Wallace *et al.*⁴. Hybridization was at 47 °C for 20 h in the same solution, containing 3 \times 10⁵ c.p.m. (0.7 ng) ml⁻¹ of labelled oligo (N-2) probe. Labelling was achieved by phosphorylating the oligonucleotides at the 5' hydroxyl end using [γ -³²P]ATP and T₄ phosphokinase (Boehringer)¹⁸. At the end of the hybridization, filters were washed successively at 0–4 °C (2 h), 25 °C (10 min), 37 °C (10 min) and 47 °C (10 min). On fluorography of the filters from this screening, one colony showed a positive signal above background; this clone was designated BIX-1 and part of the DNA insert was characterized by sequencing performed according to Maxam and Gilbert⁸. Only the coding strand is shown and this is numbered in the opposite orientation to the tetracycline resistance gene of the plasmid. The deduced amino acid sequence (top row) has been numbered according to Katayama *et al.*⁵. The 5' *Sau*3AI cloning site in the BIX-1 clone is eight nucleotides to the left of the start of the above sequence. The arrows indicate two *Hinf*II sites which give rise to a 247-nucleotide fragment (see text). Brackets indicate the start of a sequence which does not correspond to published amino acid data* (see text). The region corresponding to the oligo (N-2) probe is underlined. * Designates a nonsense codon. IXNET is 0.15 M NaCl, 1 mM EDTA, 15 mM Tris-chloride, pH 7.5.

has a DNA insert spanning nucleotides 7–108 as shown in Fig. 2, was isolated using the procedure described for the BIX-1 clone, except that oligo (dT)_{12–18} was used to initiate cDNA synthesis, and the cloned cDNA library was prepared following the homopolymer tailing method of Roychoudhury and Wu⁷. The origin of the adjacent sequence starting at residue 140 (see Fig. 2) which codes for an amino acid sequence unrelated to factor IX is not clear.

A DNA fragment (see Fig. 3 legend) was isolated from the bovine BIX-1 clone and used as a hybridization probe to screen a cloned human gene library; a positive clone, λ HIX1b, was isolated and characterized by restriction endonuclease cleavage and Southern blotting (see Fig. 3). From these results, a partial restriction map for λ HIX1b was constructed (Fig. 4A). A segment of the DNA insert containing the region that hybridizes to the bovine cDNA probe, was identified and isolated for

direct sequencing⁸. The results (Fig. 4B) reveal that, for the 96 nucleotides determined, there is 85% nucleotide sequence homology between λ HIX1b and bovine factor IX. Comparison of the amino acid sequences deduced from the nucleotide sequences shows 78% homology between the two species; note that three of the nucleotide changes are not accompanied by an amino acid change and are therefore silent changes. The degree of homology is compatible with the cross-hybridization observed between the bovine factor IX cDNA probe and the λ HIX1b clone in the rather stringent conditions used, and provides direct evidence that the latter carries an authentic DNA sequence coding for the human factor IX gene.

The present data are equivocal as to whether the λ HIX1b clone carries a complete factor IX gene. The restriction map (Fig. 4A) shows however, that the cloned segment includes more than six kilobases (kb) of DNA on one side and >10 kb

Fig. 3 Isolation and characterization of the human λ HIX1b clone. The cloned human DNA library used was a *Hae*III/*Alu*I λ Charon 4a library prepared by Lawn *et al.*¹⁸. Phage recombinants (10⁶) from this library were screened using the *in situ* plaque hybridization procedure described previously¹⁸. Prehybridization and hybridization were carried out at 42 °C in 50% formamide. After hybridization, filters were washed at room temperature with 2 \times SSC, 0.1% SDS, then at 65 °C with 1 \times SSC, 0.1% SDS. A 325-nucleotide fragment from the bovine BIX-1 cDNA clone was initially used as a probe in the hybridization. This fragment corresponds to nucleotides –8 to 317 as shown in Fig. 2, and was isolated by *Sau*3AI digestion of BIX-1 plasmid DNA. The isolated DNA was labelled to high specific activity by incorporation of [α -³²P]ATP using Amersham's nick-translation kit; 10 clones were isolated. These were plaque-purified and re-screened with a 247-nucleotide fragment from BIX-1 clone. This fragment, derived from nucleotides 3–249 (see Fig. 2), contains only sequences corresponding to the published bovine factor IX amino acid sequence⁵, and was isolated by *Hinf*II digestion of BIX-1 plasmid DNA. Only a single clone gave a positive hybridization signal with this probe. This clone was further plaque-purified and the resulting clone (designated λ HIX1b) characterized by digestion with various restriction endonucleases. Ethidium bromide-stained gels are shown on the left and their corresponding fluorograms after Southern transfer¹⁹ and hybridization with factor IX-specific 247-nucleotide probe are shown on the right. A, 1–5, cleavage pattern with *Bam*HI, *Bgl*II, *Hind*III, *Hpa*II and *Eco*RI, respectively. The sizes of the fragments showing predominant hybridization signals for these endonucleases are ~16, 11, 5.5, 6.5 and 5.5 kb respectively. B, 1, cleavage with *Bgl*II alone; 2–7, cleavage with *Bgl*II in combination with *Bam*HI, *Hind*III, *Hpa*II, *Pvu*II, *Sst*I and *Eco*RI, respectively. The sizes of the fragments showing predominant hybridization signals for these endonucleases (1–7) are ~11, 5.5, 2.5, 1.4, 1.5, 3.4 and 1.0 kb, respectively. The MW markers (kb) shown on the left are fragments from pBR322 plasmid DNA cleaved with *Alu*I, *Bam*HI + *Pvu*II and *Bam*HI + *Pst*I, plus λ DNA cleaved with *Hind*III.

Fig. 4 A, partial restriction map of λHIX1b phage DNA. B = BglII; b, BamHI; E, EcoRI; S, SstI; H, HindIII; h, HpaII; P, PvuII. The Charon 4A λ vector long arm is on the left and the short arm is on the right. Restriction sites for BglII, BamHI, EcoRI, SstI and HindIII on the vector arms are shown. The smallest fragment (~1 kb) within the human DNA insert which hybridizes to the bovine cDNA probe (Fig. 3) is a BglII-EcoRI fragment (indicated by a solid box). The construction of this map was based on the data shown in Fig. 3 and that derived from restriction analysis of a pBR322 subclone of the 10–12-kb BglII fragment containing the 1-kb BglII-EcoRI probe region. This map shows the approximate positions of the nearest restriction sites to the left and right of the probe region (with the exception of SstI and PvuII where their sites to the right have not been determined). B, Sequence of 96 nucleotides located within a region of the human DNA insert which hybridizes to the bovine cDNA probe. a, Amino acid sequence deduced from the nucleotide sequence b, for λHIX1b. These two sequences are compared with the amino acid c and nucleotide d sequence of bovine factor IX. The bovine nucleotide sequence has been numbered similarly to that shown in Fig. 2. • Indicates a nucleotide difference between the human and bovine sequences. □ Indicates a difference in amino acid between the two species. Note that the orientation of this sequence within the genomic clone is 5' to 3' from right to left.

on the other side of the sequenced region (or the 'connecting peptide region')⁵, and suggests that this segment potentially contains a complete human factor IX gene. Further sequencing should clarify this and also elucidate the structure of this gene.

Recent reports^{9,10} have described the use of specific gene probes for prenatal and antenatal diagnosis of genetic disorders. These methods are based on the observation of the existence of polymorphisms for restriction endonuclease sites which are closely linked to a particular gene locus. It is hoped that the genomic clone reported here will be similarly useful for the diagnosis and understanding of the mutations in patients with haemophilia B, as well as of heterozygote mothers who are carriers of the factor IX mutation.

We thank Dr M. P. Esnouf for gifts of the crude anti-bovine factor IX antiserum and pure bovine factor IX; Drs F. E. Baralle, N. J. Proudfoot and F. Giannelli for their help and useful discussion; and Dr M. C. Carroll for providing the BamHI-cut and phosphatase-treated pBR322 vector. This work was supported in part by MRC project grant G8103835 to G.G.B. K.H.C. is a recipient of Uncle Bobs Travelling Scholarship and a C. J. Martin Research Fellowship from the National Health and MRC of Australia.

Note added in proof: Further sequence of clone λHIX1b suggests that there is a splice point after residue 101 of the sequence (Fig. 4B, line d). The TTAG (nucleotides 98–101) may therefore derive from an intron and may not code for the amino acids L and D.

The origin of the sequence unrelated to factor IX mRNA shown within square brackets in Fig. 2 could reflect either a cloning artefact or may derive from an intron region assuming we have cloned a region of a pre-mRNA molecule. Further sequencing of the genuine clone should resolve this.

Intron-exon splice junctions map at protein surfaces

Charles S. Craik, Stephen Sprang, Robert Fletterick & William J. Rutter

Department of Biochemistry and Biophysics, University of California, San Francisco, California 94142, USA

There have been several suggested explanations for the presence of noncoding intervening sequences in many eukaryotic structural genes. They may be examples of 'selfish DNA'^{1,2}, conferring little phenotypic advantage, or they may have some importance in gene expression and/or evolution. It has been suggested that each exon (coding sequence) may represent a structural or functional unit of the encoded protein^{3,4}, for which there is good evidence in the case of immunoglobulin⁷ and haemoglobin^{8,9} genes. Exon modification, duplication and recombination may thus be general mechanisms for the rapid evolution of eukaryotic structural genes. In many cases, however, it is not apparent that an exon corresponds to some specific feature of the encoded protein^{10,11}. We describe here evidence that intron-exon junctions usually map to amino acid residues located at the protein surface, suggesting a restriction on the permitted positions of introns within a gene.

For several proteins, proteolysis cleavage points are observed at the region of the splice junctions. This implies that the junctions correspond to a location at the protein surface. For example, clostripain specifically cleaves the three arginines which exist at the splice junctions, whereas another arginine, presumably buried, is less labile⁸. Similarly, the amino acids that are cleaved in the maturation of chymotrypsin correspond

to one of the splice sites (see Table 1). In addition, in immunoglobulins and proinsulin, proteases recognize surface amino acids mapping at or near splice junctions. We therefore have examined those proteins for which both genomic sequence and protein tertiary structure are known. Unfortunately the number of examples for which these data are available is limited. We have listed in Table 1 all those proteins that we know of for which both the gene structure and tertiary structure have been determined. This data set contains 31 splice junctions for 10 protein chains containing 1,928 amino acids. For all the splice junctions in Table 1, except one (the exon A boundary of lysozyme), the splice junctions map at the surface of the protein structure (for stereo views of dihydrofolate reductase and chymotrypsinogen, see Fig. 1).

We have quantified this observation by comparing the solvent-accessible surface area of amino acids encoded at intron-exon boundaries with those located elsewhere in the protein, a residue with $\leq 20 \text{ \AA}^2$ accessible surface being defined as interior¹². Note that this calculation does not always distinguish residues at the protein surface from those within its interior. For example, in a β -sheet core or inward facing surface of a helix, the immediate environment of a residue could be exposed to a solvent channel, or a surface amino acid can be buried by the side chains of neighbouring peptides. The calculation¹³ of the solvent-accessible surface for the amino acids that map at the splice junction shows that in every case except for lysozyme, at least one and usually both amino acids that map at the splice junctions are solvent-accessible.

A statistical analysis of these data can be made by assuming we have a random sample of events for which there are two possible states; that is, the splice junction maps either at the surface or at the interior of the protein molecule. Furthermore, the junction may fall either within (class I) or between (class II) codons. In the first case, accounting for 9 of the 31 samples, the intron-exon boundary maps to a single amino acid. The solvent-accessible surface calculation was used to find the fraction of buried amino acids (Table 1, column 6). Of the 1,928

amino acids represented, 745 are not accessible to the solvent. Thus for this sample, on average 0.389 of the amino acids are buried. Class II (the remaining 22) splice junctions map between two residues, thus the accessibility of both must be considered. Here position is determined to be interior only if both residues are inaccessible. Of the 1,918 adjacent pairs in the data set, 381 or 0.199, are buried by this criterion. However, none of the pairs at intron-exon boundaries are buried. Assuming that a binomial distribution describes the probability of a splice junction mapping to the protein interior, we can calculate the expected probability for the event that up to 1 out of 9 class I, and 0 out of 22 class II junctions, are buried by chance using the formula:

$$P = \sum_{y=0}^1 \binom{9}{y} p_1^y q_1^{9-y} \binom{22}{0} p_{11}^0 q_{11}^{22}$$

where $p_1 = 0.389$, $p_{11} = 0.199$ and q_i , the probability of the junction being on the surface, is $1 - p_i$. This calculation shows that the probability P of observing only one (or zero) buried splice site for these samples is 6×10^{-4} . This calculation strongly suggests that the observed surface location of splice junctions is not coincidental.

The above observations might be explained by the restricted nucleotide composition observed around the splice junction¹⁴. This could result in a skewed amino acid composition that, in turn, might influence the location of this site within the tertiary structure of the protein. Thus, if charged amino acids were favoured there would be a 90% probability that they appear on the protein surface¹⁵. Similarly, as two-thirds of the amino acids in the hydrophobic core of proteins are Phe, Cys, Val, Ile, Leu or Met a choice from this set would tend to yield an interior splice junction. RNA sequence analysis¹² has shown that the sequence GT is nearly always found at the 5' junction, and AG at the 3' junction. We have translated in all reading frames the nucleotide sequence at the 5' and 3' side of all known splice junctions (refs 16, 17, Table 1 and unpublished data). The results show no particular constraints on the amino acid

Table 1 Solvent-accessible surface areas for intron-exon junctions in coding regions

* The amino acid residues represented are those of the protein crystal structure.

† Where the intron-exon boundary splits a codon a single residue is shown; otherwise residues on both sides of the junction are listed (see below).

‡ The precise position of the splice is sometimes equivocal due to the ambiguities of the DNA sequence around the intron-exon boundary so two amino acids are shown.

§ Five of the seven splice junctions were determined by detailed restriction and heteroduplex mapping (ref. 11 and C.S.C., unpublished).

Fig. 1 Stereo views of the α -carbon chain tracing of dihydrofolate reductase (a) and chymotrypsinogen (b) showing the location of the splice junctions mapped on the protein sequence.

composition at that 3' side of the AG at the splice site. However, at the 5' side of the GT at the splice junctions, the extremely hydrophobic, and usually buried, amino acids (Phe, Cys, Val, Ile, Leu and Met) are underrepresented by a factor of 2.1 (expected from a natural abundance of 27%, that observed here being 13%) and the extreme hydrophilic and usually surface amino acids (Lys, Arg, Glu, Gln and Asp) are overrepresented by a factor of 1.6 (expected 28%, observed 44%). We have also tabulated the codons actually used at the junction sites. Again there was no strong bias in the amino acids present at the 3' side of the splice junction, but at the 5' side, the extremely hydrophobic amino acids are underrepresented by a factor of 4.1 (expected 27%, observed 6.6%) and the extremely hydrophilic amino acids are overrepresented by a factor of 2.3 (expected 28%, observed 64%). These data indicate that a hydrophilic amino acid is indeed more common near the intron-exon splice junction and provides a bias for the location of intron junctions at protein surfaces.

It is possible that the relationship between the location of the splice junction in the gene at the surface of the protein confers a biological advantage and hence is a result of natural selection. Introns and their associated splicing systems could be exploited in many ways during the evolution of a protein. We now realize that introns do not always mark large domains of protein structure, but often mark subdomains or segments of protein structure with some function. A further generalization can be made about the location of introns from the data reported here—usually the intron positions map outside the hydrophobic core and near the surface of the proteins. The cytoplasmic proteins used here are presumably exposed to a hydrophilic environment, thus the amino acids in the region of surface splice junctions are largely hydrophilic. If the rule is general, then proteins exposed to a hydrophobic environment should have hydrophobic amino acids near the surface splice junctions. That the 'seam' of a protein should appear on its surface is not surprising from an engineering viewpoint; if we consider the consequences of joining protein segments by cavalier recombination of exons, any novel amino acid sequences that might result from the new splicing would be isolated on the surface of the protein. This provides a means for change without forfeiting the pre-existing three-dimensional structure. It might therefore be expected that protein sequences contain additions or deletions in the region encompassing the splice junction. We have shown elsewhere that the region of major variation in the serine protease family occurs at or near splice junctions¹⁷.

Our findings are in accord with previous speculations on function or nonfunction and placement of introns, but set a requirement for their location with respect to protein structure. If the surface rule for intron-exon junctions is general, then the location of splice points in genomic DNA sequences also provides useful tertiary structural information about the gene product, as certain regions of the primary sequence can be reliably predicted to reside at the surface. Thus these data might be used in part to predict aspects of tertiary structure as well as provide a strategem for the design of new proteins.

We thank David Standing and Pat O'Farrell for discussions; Graeme Bell, Carmen Quinto, Qui Lim Choo and Robert T. Schimke for communicating their sequencing data on chymotrypsin, trypsin and dihydrofolate reductase before publication; Raymond MacDonald for providing the trypsin cDNA; and Leslie Spector for preparation of the manuscript. This research was supported by NSF grant PCM 8001950 (to R.J.F.) and NIH grant AM 21344 (to W.J.R.). C.S.C. is a recipient of an American Cancer Society postdoctoral fellowship.

High-frequency genomic rearrangements involving archaeobacterial repeat sequence elements

Carmen Sapienza*, Michael R. Rose† & W. Ford Doolittle*

Departments of *Biochemistry and †Biology, Dalhousie University, Halifax, Nova Scotia, Canada B3H 4H7

Halobacterium halobium is an obligately halophilic archaeobacterium¹ of interest to molecular biologists for many reasons^{2–5}, one of which is the unexplained high frequency (10^{-4} – 10^{-2} mutants per cell plated) at which it yields readily identifiable and unstable mutants⁴. We showed previously⁵ that the genome of *H. halobium* contains many (>50) families of repeated sequences whose members are dispersed on both chromosome and plasmid. Here we report that most if not all of the members of most of these repeat sequence families effect or are affected by spontaneous genomic rearrangements. Quantitative analyses show that such repeat sequence-associated rearrangements (which may be of several kinds) occur at high frequencies (> 4×10^{-3} events per family per cell generation), while unique-sequence DNAs are physically stable. The presence of so many families of elements of such great instability in the halobacterial genome gives it an unusual degree of structural and perhaps functional plasticity.

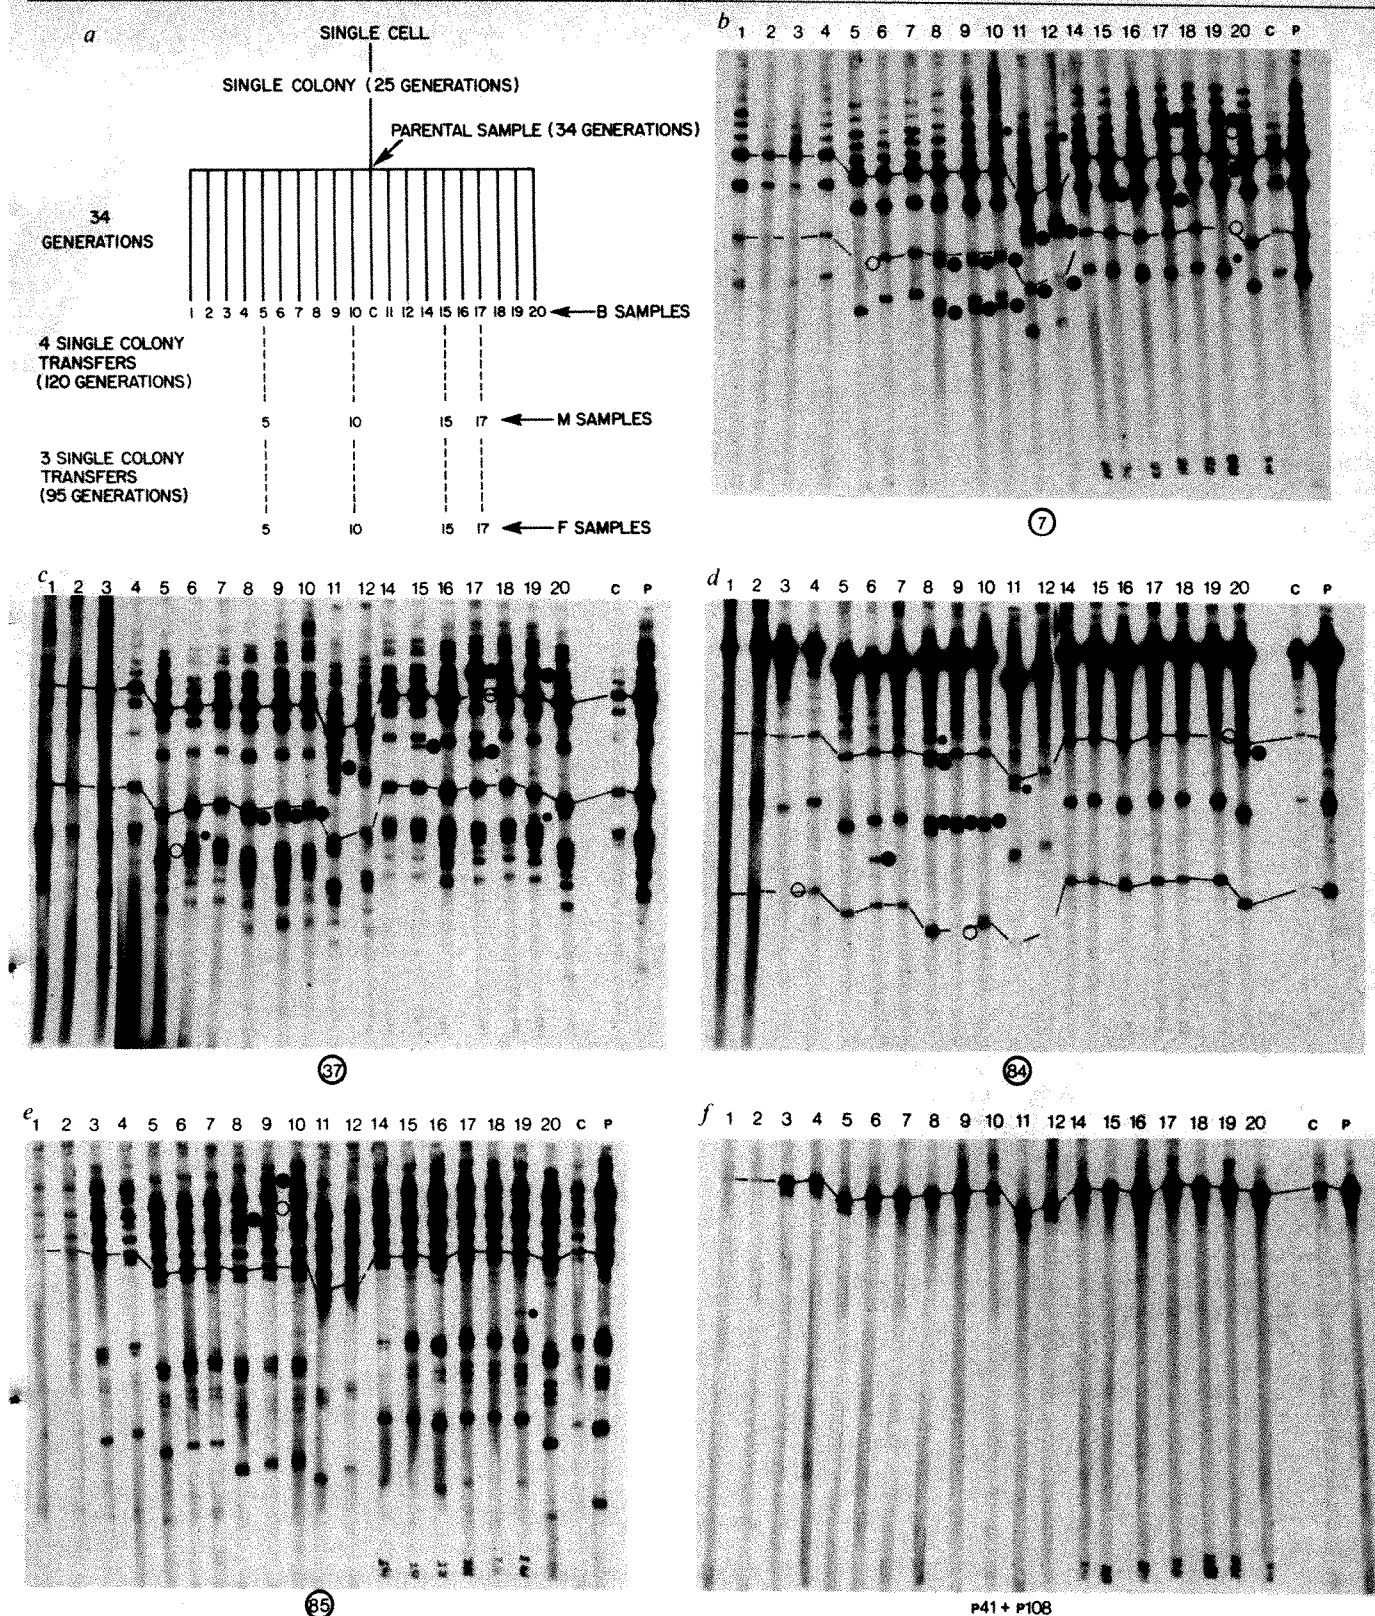

Fig. 1 *a*, Experimental protocol. A single cell of *H. halobium* wild-type strain NRC-1 was plated to give a single colony (25 generations), and cultured in liquid for a further nine generations. Most of this culture was used to prepare DNA taken to be representative of the first 'parental' cell (tracks labelled P in *b-f*). (A portion of the culture was diluted and grown in liquid for a further 34 generations, without re-plating. DNA prepared from this subculture appears in tracks labelled C of *b-f*). The rest of the culture was plated out to give single colonies; 19 of these which showed no visible phenotypic alteration were picked into liquid and grown for DNA preparation (tracks 1-19 in *b-f*). Again, 34 generations elapsed between initial plating and collection. Then four isolates (5, 10, 15 and 17) were re-plated and carried through seven additional platings and single-colony isolations. DNA was prepared from samples after four platings (120 generations, tracks labelled M in Fig. 2) and again after seven platings (215 generations, tracks labelled F in Fig. 2). The methods used for culture and DNA isolation are described in ref. 5. *b*, Results of probing *Eco*RI digestion products of the DNAs described above with cloned *H. halobium* repeat sequence element 7. ●, Hybridizing fragments present in the DNA of one of the 19 isolates which were absent from the DNA of the initial cell from which they derive (represented by tracks labelled P). ○, Hybridizing fragments absent from the DNA of one of the 19 isolates but present in the DNA of the initial cell. Hybridizations were performed as described previously⁵. *c-e*, Results for cloned repeat sequences 37, 84 and 85, respectively. *f*, Results for two cloned *Pst*I fragments of *H. halobium* DNA bearing only unique sequences.

Fig. 2 *Eco*RI-cleaved DNAs from isolates 5, 10, 15 and 17 probed with 32 P-labelled cloned repeat sequence DNAs from strain NRC-1. ◀ Indicates the position of a fragment absent from the parental DNA sample (lane P in Fig. 1b-f) but present in B, M and F DNA samples. ◁ Indicates the absence of fragments from the B, M and F DNA samples that were present in the parental DNA sample. ■, Hybridizing fragments in the M and F DNA samples not present in B DNA samples; □, fragments hybridized in B DNA samples but absent from M or F DNA samples. ●, Fragments hybridized in only M or F DNA samples; ○, fragments absent from F but present in B and M DNA samples. a and b are results of probing with repeat sequence clones 37 and 85, respectively.

We described previously⁵ the molecular cloning and characterization of small (~3 kilobase pair, kbp) *Eco*RI fragments of *H. halobium* DNA bearing members of one or more repeat sequence families of small family size (2 or 3 to perhaps 20 members). Preliminary experiments with two of these fragments suggested that such repeated elements could be affected by spontaneous genomic rearrangements. These experiments provided no information, however, on the frequency or nature of those rearrangements, nor did they elucidate whether such instability is associated only with repeated elements and, if so, whether all families, or all members of any family, exhibit instability.

The experiments shown schematically in Fig. 1a measured rates of spontaneous rearrangement in 19 cell lines separated from a common ancestor by only that minimum number of generations (in practice, 34) required for the preparation of sufficient DNA for Southern blot analyses^{5,6}. *Eco*RI-digested total DNAs from each of these 19 isolates were resolved on agarose gels, transferred to nitrocellulose filters and probed with 32 P-labelled, *Eco*RI-cloned *H. halobium* fragments bearing members of seven distinct repeat sequence families⁵. Results obtained with four of these probes are shown in Fig. 1b-e. Many changes in both number and position of hybridizing fragments are apparent. If each independent appearance or disappearance of a hybridizing fragment is defined as an event, there were 56 different events among the 19 isolates which were uniquely detected by one or another of the seven repeat sequence probes. All such probes detected events in at least one of the isolates and we believe that all repeat sequences are associated with genomic rearrangements occurring at high and roughly comparable frequencies. On the other hand, two unique-sequence DNA probes detected few if any changes in any of the isolates (Fig. 1f).

If genomic rearrangements involving repeat sequences occur independently, then the observed frequency of events (roughly 10^{-2} per repeat sequence family per cell generation) could be taken as the probability of such rearrangements occurring in any cell line (isolate). However, events were not randomly distributed among isolates. Four isolates together accounted for about half the events and one showed alterations with five of the seven repeat sequence probes, while seven isolates showed no changes with any probe. If we assume that one event is usually coupled with others, then the probability of that first

event (assumed to be the same for all repeat sequence families) provides the most conservative estimate of rearrangement frequency. This can be calculated from the observed frequency of isolates exhibiting no changes using the zero-term of the binomial distribution. That is, the probability of change, P , can be calculated from the observed frequency ($7/19 = 0.368$) of isolates showing no alterations in 34 generations, using the equation $0.368 = [(1 - P)^{34}]^7$. This use of the binomial distribution assumes that rearrangements depend on independent Bernoulli trials over seven families. If rearrangements can arise at any time, however, a similar calculation using the zero-term of the Poisson formula is more realistic⁷. Both calculations give values for P of 4×10^{-3} events per repeat sequence family per cell generation (or from 4×10^{-4} to 1×10^{-3} per repeat sequence element). This is not remarkably lower than 10^{-2} , our observed frequency irrespective of order, because events are only partially coupled. From these values, we predict that about one-tenth of all isolates will experience rearrangements affecting at least one of the seven repeat sequence families during the first three or four divisions after their establishment from single cells. Such rearrangements will give rise to restriction site polymorphisms detectable as weakly hybridizing fragments in the DNA prepared after 34 generations. Weak bands were indeed detected for several isolates and with several probes and were, as far as possible, excluded from our calculations.

Of the nine *Eco*RI fragments probed strongly by the repeat sequence family member carried on clone 7, five have been deleted in one or another of the isolates characterized here (Fig. 1a) or previously⁵. This suggests that all members of at least this repeat sequence family are equally liable to exhibit genomic rearrangement. To determine whether the 'new' hybridization patterns produced by rearrangement are as stable as 'old' ones, 4 of the 19 isolates (Fig. 1a) were carried through seven further single-colony isolations, with DNA prepared as above after the fourth (120 generations) and seventh (215 generations) platings. These DNAs were probed with five cloned *H. halobium* repeat sequence DNAs and two cloned repeat sequence DNAs from *Halobacterium volcanii* previously shown to be homologous with two different *H. halobium* repeats⁵ (Fig. 2 and data not shown). In none of the three cases in which one of these four isolates had lost a hybridizing fragment during the first 34 generations was that fragment regained during 215 subsequent generations; vacated sites

appear not to be selectively reoccupied. In only one of the four cases in which one of these four isolates had gained a new hybridizing fragment during the first 34 generations was that fragment lost during the subsequent 215; newly-occupied sites do not appear to be uniquely unstable. Other changes observed during the propagation of these four isolates occurred with a frequency ($\sim 2 \times 10^{-3}$) in reasonable agreement with that obtained from the more extensive survey reported above.

The events observed result in either: (1) the appearance of a new hybridizing fragment without the loss of pre-existing fragments; (2) the loss of a pre-existing fragment without the appearance of a new one; or (3) the appearance of a new fragment and the loss of a pre-existing fragment, at about the frequency expected for independent occurrences of events of the first two types in the same cell line.

There is substantial indirect qualitative evidence^{4,8} for the transfer of discrete DNA sequences between plasmid, phage and chromosomal DNAs and we believe that many of the events whose frequency we have measured here are probably at least formally analogous to transpositions, although we cannot exclude alternative interpretations invoking deletions and duplication via unequal cross-over events between repeats of the same family. Whatever the nature of these events, the high frequency with which they occur in all repeat sequence families tested, and the large number of such families, must give the halobacterial genome an unusual degree of structural plasticity. It is easy to calculate that two daughter cells produced by a single division have only an 80% chance of bearing identical genomes, and that of the 10^{11} progeny in a 1-l culture established from a single cell, only 3×10^7 will bear genomes identical to that of the first cell, if all rearrangements are selectively neutral. They are not likely to be, and questions about the functional significance of this genomic plasticity and its relationship to the observed high frequency of spontaneous mutation are of considerable interest.

We thank the MRC of Canada for support, A. Cohen for technical assistance and N. Kleckner for critical advice.

The helicity of DNA in complexes with RecA protein

Andrzej Stasiak & Elisabeth Di Capua

Institute for Cell Biology, Swiss Federal Institute of Technology, Hoenggerberg, CH-8093 Zürich, Switzerland

The RecA protein of *Escherichia coli* is involved in recombination (for review see ref. 1). The protein binds transiently to double-stranded DNA in the presence of ATP. In the presence of ATP γ S, a non-hydrolysable analogue of ATP, recA-DNA complexes are stable^{2,3}. Duplex DNA in these complexes is stretched by a factor 1.5 (ref. 4), and the complexes appear in the electron microscope as helical filaments with a pitch of ~ 100 Å and 6.2 recA units per turn covering 18.6 base pairs (bp)⁵. RecA crystals have a space group of similar helical parameters⁶. In order to understand the function of recA, it is necessary to describe the conformation of the DNA in the recA complex. Using a topological method, the present work determines the helicity of DNA in the complex. We find that the DNA helix follows the protein helix visible in the electron microscope and has 18.6 bp per turn, which corresponds to an unwinding of the DNA double helix by 15° per bp.

Fig. 1 Nicked circular DNA fully covered with RecA protein (a) and topoisomers of different linking numbers α reacted with RecA protein, $\alpha = 432$ (b), 445 (c), 459 (d), 472 (e). Note that in b to e the rod-like striated structures arise from side-by-side aggregation of neighbouring segments of the same circular RecA-DNA complex, while the thin filaments represent the highly positively supercoiled segments not covered by RecA. The cross-striations visible are due to the helical structure of the RecA-DNA complexes described in more detail in ref. 5. This helical structure is identical by our criteria whether the complexes are made with relaxed or cccDNA. The plasmid used is a pBR322 derivative of 4,961 bp. The topoisomers were produced by reacting plasmid DNA (100 μ M bp) with nicking-closing extract from rat liver nuclei¹³ in the presence of 0 μ M (b), 6 μ M (c), 12 μ M (d), 18 μ M (e) ethidium bromide. The recA-DNA complexes were obtained by incubating 50 ng DNA with 2.5 μ g RecA protein and 2 mM ATP at room temperature in 20 μ l 25 mM triethanolamine chloride (pH 7.6) and 5 mM magnesium acetate, conditions which seem to permit initiation of binding of RecA to cccDNA. After 20 min, ATP γ S to 0.5 mM was added to stabilize the complexes and the reaction was continued for 1 or 24 h at room temperature. The extent of reaction was the same after both times of reaction, thus implying that the reaction was complete after 1 h. Control experiments with different RecA-DNA ratios gave the same extent of DNA covering by RecA for a given DNA sample. Thus, in our experimental conditions, the extent of reaction is not a function of RecA:DNA ratio (see also ref. 4).

Double-stranded DNA has been shown⁷ to be unwound to some extent by RecA. We have now found conditions that allow the formation of complexes with covalently closed circular (ccc) DNA, and this enables us to determine the extent of this unwinding by a topological approach. A cccDNA molecule is characterized by its linking number which is fixed⁸; thus, reac-

Fig. 2 Determination of the linking number of a cccDNA fully covered with RecA. The linking numbers were calculated by assuming 10.5 bp per turn of B-DNA in solution^{10,11}, which results in 472 turns for 4,961 bp, and subtracting from this value the number of superturns determined from the maximum of the distribution on band-counting gels⁹. For each topoisomer family the extent of covering with RecA was determined from 15–25 molecules. The standard deviation for each point was 2–3%, which is compatible with the presence of 7–8 topoisomers in each sample as seen on the band-counting gels. Extrapolation to 100% covering with RecA leads to a value of 267 ± 19.2 for the linking number of a totally covered molecule. The confidence interval was drawn assuming 95% confidence.

tion with an unwinding agent will lead to a topological constraint in the molecule, and it is to be expected that the binding of the unwinding agent will stop when this constraint reaches a limit. The linking number will then be the sum of the underwound and overwound turns. In the case of RecA protein, which covers the DNA cooperatively⁴, we found (Fig. 1) that the underwound and the overwound regions are distinct and easily recognizable as striated complexes and highly supercoiled tails, respectively. Thus, the fraction of the molecule that is allowed to undergo complex formation can be measured. The linking number α is related to this complexed fraction by

$$\alpha = \frac{f_c n + f_t (N - n)}{360}$$

where n is the number of base pairs complexed with RecA, f_c the topological winding angle of the DNA complexed with RecA, N the total number of base pairs of the molecule and f_t the topological winding angle of the DNA not covered with RecA (recognized as a tail in Fig. 1).

If we now determine the extent of covering by RecA on cccDNA molecules of different α , the values of f_c and f_t can be determined by extrapolating the relationship to $n = N$ (completely reacted), and $n = 0$, respectively (Fig. 2). The angles f_c and f_t are assumed to be independent of α , that is, the constraint in the tail will be constant per unit length. We assume that this tail takes up a limit value of positive supercoils. Note that the values of f_c and f_t are the result of two orders of helicity, the primary helix of the DNA (in the covered part and in the naked tail respectively), and a secondary helix. In the case of f_t (uncovered tail) the second order helix is the positive supercoiling caused by torsional stress. In the case of f_c (complex) the second order helix is inherent in the structure of RecA-DNA complexes associated side by side (visible as turning-over points⁵) and is not caused by torsional stress; since this second-order helicity in the complexed part contributes only 2.6% to the linking number we do not take it into account here, and consider simply the overall unwinding.

cccDNA molecules of various linking numbers were obtained by reacting plasmid DNA with nicking-closing enzyme in the presence of various amounts of ethidium bromide. After purification of the products, the amount of unwinding was determined by estimating the supercoiling on band-counting gels⁹. Unfortunately, using the band-counting technique it is

difficult to determine precisely the linking number of highly supercoiled molecules above a superhelical density of 0.1. This limited the range in which the linking number and the extent of RecA covering could be related precisely. A series of cccDNA molecules of various linking numbers complexed with RecA protein is shown in Fig. 1; a relaxed complex formed with nicked DNA (thus allowing 100% complex formation) is shown for comparison. It is seen that the lower the linking number, the more RecA is bound. In Fig. 2, the extent of covering with RecA is plotted against the linking number. Least-squares analysis fits the data to a straight line with a correlation factor of 0.99. Extrapolation shows that 100% covering of DNA by RecA would require a linking number of 267 ± 19.2 (confidence 0.95). From our previous work, we know that a relaxed circular molecule of 4,961 bp will form a complex with 267 or 268 visible helix turns (ref. 5, and Fig. 1a). The linking number calculated above from Fig. 2 is very close to this number. We thus conclude that the RecA-helix seen in the electron microscope reflects the helix of the DNA molecule within the complex.

It is interesting to point out that the RecA self-complexes (that is, filaments formed in the absence of any DNA) form a similar helix as far as we can judge from our electron micrographs (see also ref. 2). By interaction with RecA protein, double-stranded DNA is unwound from about 10.5 bp per turn^{10,11} to 18.6 bp per turn. This corresponds to an unwinding of 15° per bp, a value similar to the unwinding by ethidium bromide (26° per 2 bp¹²) and is thus compatible with the intercalation type of interaction we suggested to explain the stretching of DNA in the complex⁴. We cannot exclude, however, the possibility that the DNA in the complex is melted and the single strands are wound around each other without forming a base-stacked helix.

We thank Professor Theo Koller for his help and support, Philipp Bucher for help with the calculations and Dr Martin Gellert for stimulating comments. This work was supported by Schweizerischer Nationalfonds zur Förderung der wissenschaftlichen Forschung (grant to Th. Koller).

Errata

The cover photograph on the issue of 22 July, relating to the letter 'Monoclonal antibodies against human T lymphocytes label Purkinje cells of many species' by J. A. Garson *et al.* *Nature* **298**, 375–377 (1982), was reproduced in only two colours so that orange and green staining was not sufficiently differentiated. The photomicrograph shows neonatal mouse cerebellar cortex stained with two monoclonal antibodies simultaneously. The Purkinje cells are stained orange by Leu-4/biotin/avidin/rhodamine, while basket fibres and other axons are stained green (fluorescein conjugate) with the antineurofilament monoclonal RT97 (donated by B. Anderton).

In the article 'Dynamic observation of defect annealing in CdTe at lattice resolution' by R. Sinclair *et al.* *Nature* **298**, 127–131 (1982), parts *c* and *e* of Fig. 3 have been transposed thus interrupting the movement of the arrowed dislocation across the frame. The figure is correct on reprints.

MATTERS ARISING

Absence of thermal effects on photon mass measurements

THE mass of the photon^{1,2} is known to be less than 10^{-16} eV. However, in a letter to *Nature*, Primack and Sher³ have questioned the validity of this result. They suggest that electrodynamics may undergo a phase transition at low temperature, and point out that all of the photon mass experiments took place at temperatures above a few degrees Kelvin. Thus, they claim that the above mass limit may only apply to a high-temperature phase ($T > T_c$ where T_c could be as large as a couple of degrees Kelvin), and that when measured at lower temperatures the photon mass could be as large as about 10^{-4} eV. Apparently, low-temperature photon mass experiments are presently being considered⁴. We explain here why we believe that the scenario proposed by Primack and Sher³ is, in fact, impossible. We find that the limit of 10^{-16} eV on the mass of the photon is unaffected by the fact that the relevant experiments were performed at finite temperature. It is therefore completely valid and applies to experiments regardless of whether they are carried out at room temperature or at absolute zero.

To analyse thermal effects on measurements of the photon mass we must define what is meant by a phase transition in finite temperature field theory⁵⁻⁷. At zero temperature, the vacuum and the various particle states are described by definite state vectors. We can study vacuum expectation values of different field operators and we can measure the photon mass by examining how a photon propagates through the vacuum. At non-zero temperature, the system is described by a density matrix. We can no longer consider vacuum expectation values, but instead we deal with thermal expectation values. At finite temperature space is filled with thermal radiation and to measure the photon mass we must determine how a photon propagates through this thermal radiation. It is important to note that the vacuum does not change with temperature. However, quantities like field expectation values or particle masses can change because at non-zero temperatures they are measured not in the vacuum but in a thermal ensemble.

Therefore, we must ask what is the nature of the thermal fluctuations which occur at or below room temperature, and how can these affect the measured value of the photon mass? In particular, are the interactions of the photon with the thermal fluctuations at these temperatures strong enough to make a massive photon appear massless? The mass of a field sets a lower limit on the energy of its small fluctuations so a field of mass m will only experience significant fluctuations at tem-

peratures $kT \geq m$. At room temperature or below the only relevant thermal radiation consists of blackbody photons. Note that if there existed a fundamental or composite scalar field with a small vacuum expectation value which gave the photon a mass, then this field would only experience significant thermal fluctuations at normal temperatures if it produced a charged scalar particle with a mass of a fraction of an eV. If the associated charge scalar were heavier than this then thermal fluctuations of this scalar field would be exponentially suppressed. Since no such light charged particle exists we conclude that there is no way for thermal fluctuations to change the expectation value of such a field and thereby change the photon mass from some non-zero low-temperature value to zero at room temperature. However, we must still consider the effect of thermal photons on the photon mass at finite temperature.

The real-time thermal propagator for a particle of mass μ is

$$\frac{i}{k^2 - \mu^2} + \frac{2\pi}{e^{E/kT} - 1} \delta(k^2 - \mu^2) \quad (1)$$

The temperature-dependent term in this propagator is multiplied by $\delta(k^2 - \mu^2)$ so thermal effects are completely absent, to lowest order in α , for off-shell, virtual photons. The best limits on the photon mass come from measurements of the static magnetic field produced by Jupiter and these involve virtual photons. The second term in equation (1) is only relevant for real, on-shell photons of energies $E \leq kT$. For these photons this term represents the stimulated emission effect which the presence of thermal photons produces. Equation (1) is of course modified by order α corrections due to the interactions between thermal photons and a propagating virtual photon. However, such interactions occur only through loops of charged particles and are suppressed by a factor $e^{-m/kT}$ where m is the mass of the charged particle. The lightest charged particle is the electron and it produces polarization factors,

$$\Pi_{\mu\nu} \propto e^2 m_e^2 \left(\frac{m_e}{kT} \right) e^{-m_e/kT} \quad (2)$$

At temperatures of order room temperature or below, the factor $e^{-m_e/kT}$ is a gigantic suppression factor so these thermal effects are completely negligible. Thus, a virtual photon propagating through thermal radiation at normal experimental temperatures is completely unaffected by the presence of that radiation simply because no mechanism exists for it to interact in any appreciable way with the thermal photons. It follows that experiments which determine how a virtual photon propagates, like the photon mass experiments, will be unaffected as well. The photon mass limit of 10^{-16} eV is therefore valid at low temperature.

We wish to thank Alvaro DeRujula for

SHER AND PRIMACK REPLY—In our paper, we explained that neither spontaneous nor dynamical symmetry breaking could lead a mass for the photon at low temperature; but we speculated that some other physical mechanism could conceivably do it, and we pointed out that the question could be decided experimentally. Abbott and Gavela argue again that spontaneous symmetry breaking (the 'Higgs mechanism') will not work. The essential physical point they make is that "... a field of mass m will only experience significant fluctuations at temperatures $kT \geq m$." We agree. The question is whether the absence of charged particles (either bosons, mentioned by Abbott and Gavela, or fermions) lighter than the electron excludes an electromagnetic phase transition at $kT < m_e$, even one arising from a hitherto unknown mechanism. We are persuaded that their argument indeed excludes this possibility.

It should be noted that this argument could affect other, more realistic calculations. There have been many calculations of supercooling in both SU_5 and the Weinberg-Salam model. In some of these, the mass (at $T=0$) of the scalar before the transition vanishes (Coleman-Weinberg); the field can then experience significant fluctuations. In some, however, the scalar does have a small but non-zero mass m (see ref. 1). The argument of Abbott and Gavela appears to rule out a transition at $T \ll m$; completing a transition at such a temperature may not be possible (if only the Higgs potential is considered; massless fermions could condense and drive the transition if the coupling constant is large enough).

Crystal instability and melting

COTTERILL AND MADSEN¹ argue against an essential connection between thermodynamic melting and crystal instability. Their molecular dynamics simulation of a 336-particle Lennard-Jones (LJ) assembly revealed the existence of a dislocation-mediated mechanical instability in the superheated crystalline phase at a density ($\rho_{\text{inst}} = 1.22$) lying just outside the melting interval ($\rho_{\text{cryst}} = 1.38$, $\rho_{\text{liq}} = 1.24$) determined by Hansen and Verlet² for the same isotherm. Moreover, with increasing temperature, the instability was progressively further removed from the melting interval. We suggest, however, that contrary to their hypothesis, these results add further to an already substantial weight of evidence for the essential connection between crystal instability and melting^{3,4}.

Born⁵ was among the first to propose that melting occurs as a mechanical instability when one of the crystal shear moduli falls to zero. Of course, experiment demonstrated that the shear moduli remained finite up to the melting point, but we have shown^{6,7} that extrapolation of one of the shear moduli as a function of density beyond the melting point, reveals that it would fall to zero at the freezing density for a wide range of ionic, metallic and molecular crystals. We interpreted this as implying the universal existence of an instability concealed between the melting and freezing lines but lying close to the latter. This is confirmed by theoretical calculations for alkali halides⁸ and, indeed, is what one would expect from a proper interpretation of Born's melting criterion. If the crystal were superheated to the critical density, ρ_c , of vanishing static shear modulus, the resultant localization of shear modes would contribute an additional amount, $R \ln 2$, to the entropy⁸, so that the system would be able thermodynamically to make an isothermal jump from a lower density, ρ_{cryst} , to the density, ρ_c . Thus the instability, in normal circumstances, would be concealed by the first-order transition, and to a first approximation ρ_c ($= \rho_{\text{inst}}$) may be equated to ρ_{liq} .

The molecular dynamics result of Cotterill and Madsen seems to confirm our original interpretation of Born's melting criterion, since the freezing density and instability density are almost coincident. Both the suppression of long-wavelength phonons in their finite (336-particle) system and critical slowing would serve to delay the instability and thus it lies a little beyond the melting interval, and is displaced further away with increasing temperature.

Note also that the single-cell occupancy system simulated by Hansen and Verlet to obtain a reversible path between liquid and solid, probably has a first-order transition (L. V. Woodcock, personal communication) rather than the second-

Fig. 1 LJ glass transition temperature (T^*) as a function of density (ρ). The expected transition temperature on Cotterill and Madsen's isotherm is indicated by the arrow.

order transition assumed by Hansen and Verlet. Their phase boundaries may not therefore be altogether reliable. We note that the actual freezing line for argon is displaced progressively away from the Hansen and Verlet line in the same manner as the instability line.

Finally, Cotterill and Madsen's location of the glass transition between the melting and freezing lines at $\rho_g = 1.29$ seems incorrect. Their procedure of finding the intersection of extrapolated linear fits of the extremes of their isothermal pressure-density data ignores the fact that the isotherms are naturally curved in any one phase. Figure 1 shows LJ glass transition temperatures as a function of density reported by Abraham⁹ (squares) and Damgaard-Kristensen¹⁰ (circle) and this predicts a glass transition on Cotterill and Madsen's 0.77 isotherm at $\rho_g = 1.401$; that is, well above their value $\rho_g = 1.29$, and outside the melting interval. That their glassy pair and bond angle distribution functions (pdf and adf, respectively) are actually evaluated for supercooled liquid is evidenced by the lack of a fully developed split-second peak in the pdf. Presumably the incipient splitting in their adf at 110° and 120° would be fully developed in a true glass.

COTTERILL AND MADSEN REPLY—Tallon considers our instability density for $T = 0.75$ to be indistinguishable from the freezing density, within computational error, and dismisses the disparate temperature dependencies with a reference to real argon, despite its differences from the pseudoinfinite Lennard-Jones matter studied by Hansen and Verlet¹ and ourselves². Moreover, the discrepancy between the two materials is opposite to Tallon's claim. We cannot see why model-dependent stabilization, beyond the instability point, should be more effective at higher temperature. Melting is a reversible first-order transition, the location of which depends on the properties of both liquid and crystal. Instability theories attempt comprehensive treatment of the transition, including projections of liquid properties, using exclusively crystalline characteristics. Such unilateral approaches are inferior to those incorporating more realistic concepts of liquid structure.

Because the properties of all three condensed states are nevertheless determined by the same interatomic interactions, empirical correlations between properties are inevitable; the proximity of the instability and freezing densities²⁻⁴ is thus hardly surprising. But vacancy⁵ and dislocation⁶ parameters both also correlate with the melting temperature, even though melting theories based on these two defects are mutually exclusive⁷. We show elsewhere⁸ that the excess entropy of liquids over crystals is associated with fluidity, not disorder, and stems from conversion of transverse phonons to diffusive modes⁹. Tallon's rather nebulous analysis¹⁰ fails through, amongst other things, neglecting the entropy associated with perfect crystal oscillatory modes. The location of the glass transition density is subject to a choice of convention, but a density of 1.4 for $T = 0.77$ is irreconcilable with our findings; the pressure varies linearly with density in the range 1.35–1.45. Applying Abraham's convention¹¹ to our data, or vice versa, produces no contradiction.

BOOK REVIEWS

A disappearing breed

Brian Bertram

WITH the publication of Vols IIIC and IIID of *East African Mammals*, Jonathan Kingdon has completed his *tour de force*. These final volumes deal with most of the artiodactyls — the bovines and antelopes whose numbers and diversity contribute so much to the array of East Africa's mammals.

The format is the same as in the earlier volumes. For each tribe the author presents an introductory profile covering topics such as structure, coat colouring, the form of the horns, body size, evolutionary history, signalling and ecological niches. For each species he then describes its past and present distribution, its distinguishing features, its feeding and predators, its behaviour and breeding. Again, the author's superb illustrations abound, and contribute greatly to the information presented; Kingdon can convey so much more with a few pencil lines than anyone could say in many pages of text. There are always beautiful and meticulously accurate drawings of the whole animal, and there are often equally accurate drawings of the skinned animal, revealing the underlying musculature, and of the skeleton. In addition, there are countless thumbnail sketches which capture the essence of an animal's appearance or behaviour.

Unlike earlier volumes in the series, neither of these final volumes can stand on its own. Volume IIIC includes the bovines and the smaller antelopes, while Vol. IIID has the larger antelopes, four appendices, the bibliography and indexes for these last two volumes, and a species checklist for all seven volumes. The first appendix outlines the fundamental problems of conservation, and the ethic, the threats, and the meagreness of the response. The second, by David M. Jones, summarizes current knowledge of the feeding and handling of mammals in captivity. Appendix III lists the various parasites and diseases known to infect

East African Mammals: An Atlas of Evolution in Africa, Vols IIIC and IIID. By Jonathan Kingdon. Vol. IIIC, pp.393, ISBN 0-12-408344-7; Vol. IIID, pp.353, ISBN 0-12-408345-5. (Academic: 1982.) Each volume £49.95, \$99.50.

East African mammals, and Appendix IV considers briefly the potential for commercial exploitation of wildlife.

We can now look back on the whole series, and we must do so with considerable awe. The 2,900 pages contain a vast wealth of information and discussion. They also contain hundreds of fascinating and often most beautiful illustrations. Particularly in the earlier volumes, more guidance could have been given to help the reader to make use of the illustrations, noting important features or explaining what an animal was doing. But it remains indisputable that these seven books constitute a remarkable work.

The art of Jonathan Kingdon — a Greater Kudu from Vol. IIIC of East African Mammals. A limited edition of full-size illustrations from the series has also been published. Details can be obtained by writing to Pangolin Prints, PO Islip, Oxon, UK, enclosing a stamped, addressed envelope.

The series has expanded in the writing. "This is the first of a three volume work" announced the flysheet to Vol. I, in 1971. By geometrical progression, this was followed by IIA and IIB, and by IIIA, IIIB, IIIC and IIID. It has been a somewhat unplanned growth, resulting in some awkward anomalies of arrangement: thus the page numbers in Vols IIB and IIID, but only these, continue from where the previous volumes' numbers left off; the bibliographies are sometimes split up according to subject and sometimes not; and what is essentially the same gazetteer appears in Vols I, IIB, IIIA and IIID.

Expansion plus inflation have had an alarming effect. On publication eleven years ago, the 446 pages of Vol. I cost £12 (about £38 at today's prices), and a reprint can still be bought for £34.40. The 353 pages of Vol. IIID will cost you £49.95, and the whole series £255 (\$534.50), which means that what started as a set of three, which keen private naturalists could just hope to afford, has ended as a series mainly for libraries. It is well worth making sure you have access to it somehow, because it contains so much of value as well as of beauty.

Valuable beautiful things are rare, and so may well prove to be good investments. On their current form these books will be. But I fear that the series, like its author and like several of the species it describes, is a disappearing breed. The very high standard of production, the generous use of space, the large typeface and the ample illustrations all allow what have become increasingly reference works for the specialist and the professional to retain the attractiveness of coffee table books. What a pity it is that other continents and other faunas have yet to be so well served by anyone as East Africa has by Jonathan Kingdon and Academic Press. □

Brian Bertram is Curator of Mammals at the Zoological Society of London.

And citation begat co-citation . . .

A.C. Allison

ISI Atlas of Science: Biochemistry and Molecular Biology 1978/80. Pp.540. ISBN 0-941708-00-4. (Institute for Scientific Information, Philadelphia: 1982.) \$45 (individual), \$90 (institution).

THE information explosion is daunting to most people but challenging to others, including Eugene Garfield and his colleagues of the Institute for Scientific Information (ISI) in Philadelphia, who have devoted themselves to the systematic collection and organization of information. First came *Current Contents*, the usefulness of which is universally acknowledged. The commercial success of *Current Contents* allowed the production of the *Science Citation Index*, which is widely but less generally used. More recently the Institute has published *Research Fronts in ISI/Biomed* and now the *ISI Atlas of Science*, a reference work to 102 Research Fronts or "Specialties" within the fields of biochemistry and molecular biology.

The Research Fronts included in the *Atlas* were identified by frequent citations in the *Science Citation Index*. The central process of selection of papers was the process termed "co-citation clustering". This is when an author, in citing the works of two other authors, establishes an intellectual link between them. The papers quoted in the *Atlas* were both highly cited and frequently co-cited. This computer analysis is supposed to reveal sets of papers that are important, because of the attention they have received from colleagues of the authors, and highly related because of the co-citation linkage. For each specialty, maps are constructed in which the documents are arranged graphically according to a mathematical treatment of co-citation patterns. The same treatment is also used to construct a Global Map, which shows the relationships among the various specialties in biochemistry and molecular biology.

For each specialty there is a section entitled "Citation Core Documents" which comprises the main citations and co-citations constituting the cluster. This is intended to provide objective assessment of clustering and case documentation, instead of the usual subjective assessment by individual scientists. There is a short, one-page mini-review of each specialty.

The unique feature of the *Atlas* is the Specialty Maps and the Global Map, but it can be questioned whether this is the most useful way to employ computers. The value of computers for information retrieval, especially for recovering associated information (e.g. on prostaglandins in a particular cell type) is well established and has lightened this burden for most scientists. Listing the Citation Core Documents for each specialty is helpful,

although similar information can be obtained through the *Index Medicus* and other compilations. A brief perusal of these documents will often establish their relatedness more surely than the maps, which are for the most part statements of the obvious and are at times misleading.

It can also be questioned whether, for persons intending to go into a field seriously, reviews of specialties by various experts, such as are found in the *Annual Review of Biochemistry*, do not provide

equally accessible and more authoritative and up-to-date sources of information than the data in the *Atlas* (most of the analyses in the *Atlas* were completed before 1980, but supplements refer to major citations in 1980).

The general conclusion is that the thirst for information is not easily satisfied, and that the *Atlas* does provide a ready source of information on a range of subjects. Certainly, it is likely to be widely sold and used. □

Mitochondria: the cell's paying guests?

M. J. Selwyn

Mitochondria. By Alexander Tzagoloff. Pp.342. Hbk ISBN 0-306-40799-X; pbk ISBN 0-306-40778-7. (Plenum: 1982.) Hbk \$42.50, £26.78; pbk \$19.95, £12.57.

MITOCHONDRIA have provided interesting and challenging subjects for study by biochemists and cell physiologists ever since it became possible, in the early 1950s, to isolate them in quantity and quality. The reason for this interest is that the organelles have an integrated set of functions which, although complex, is more simple than that of a whole cell; for instance it was soon recognized that they contained complete sets of enzymes for the citric acid cycle and fatty acid oxidation. In his new book, Alexander Tzagoloff appropriately describes these metabolic pathways in brief, in only one of the eleven chapters; most readers can be expected to be well acquainted with them.

The central chapters of *Mitochondria* deal with the properties and functions of the membrane-bound enzymes and carrier systems, including the vital function of regenerating ATP by oxidative phosphorylation. The story of the investigation of these systems should be a fascinating and salutary tale. The classical techniques and concepts of aqueous phase biochemistry failed to resolve the mechanisms, and new methods and ideas for membrane biochemistry had to be developed. Sad to say I found this, the longest and a very important section, somewhat disappointing. The author appears to give unenthusiastic acceptance to the chemiosmotic coupling theory and these chapters are not as up-to-date as they should be, few papers after 1978 being cited. The treatment is patchy and sometimes falls far short of what is needed. For example, descriptions of ions simply as "permeant" can be misleading, as is describing uncouplers as "blocking" reactions; and are we really not sure that

valinomycin is a mobile carrier and gramicidin a pore-former? The failure to describe the proton-conducting function of the membrane-embedded component detracts seriously from the treatment of the ATPase complex.

The last two chapters, on mitochondrial biogenesis and genetics, make more exciting reading. Over the past 20 years mitochondria have been found to contain not only their own DNA but a complete apparatus for synthesizing a few polypeptides. And whilst a decade ago the mitochondrial protein synthesizing system appeared to be very similar to that of prokaryotes, major differences are now being discovered — not only between the mitochondrial and prokaryotic systems but also between mitochondrial systems from different organisms. The idea that mitochondria are the descendants of symbiotic prokaryotes which paid for their keep in the ancestral eukaryote cell by regenerating ATP is now no more plausible than the alternative that mitochondria arose by segregation of certain functions and some DNA within the eukaryote. Whichever is the case, it is clear that mitochondria are now set to be a testing ground for fundamental investigations in molecular genetics and into the evolution of eukaryotic cells.

Tzagoloff helps to fill the gap left by the failure to revise Lehninger's *The Mitochondrion* since it first appeared in 1964. He provides much of the basic material which a research student working with mitochondria will need to know. Teachers of advanced undergraduate courses will also want a copy, and one or two in the library, but they will have to supplement and comment on the bioenergetics chapters. □

On the edges of the sea

John H. Steele

Ecology of Coastal Waters A Systems Approach By K H Mann Pp 322 Hbk ISBN 0-632-00669-2, pbk ISBN 0-632-00953-5 (Blackwell Scientific/University of California Press 1982) Hbk £25, \$36, pbk £10 80, \$18

COASTAL ecosystems are very diverse, reflecting the many different ways in which the land interacts with the sea. This coastal zone has always fascinated biologists and, more recently, has become subject to increasing pressure for recreational and commercial uses. Thus, for both scientific and practical reasons, we need to generalize about these environments. Dr Mann's book approaches the problem in two ways — by description of the principal types of coastal ecosystem and by considering the application to these systems of various modelling techniques.

Coastal waters are often considered as the most accessible parts of the pelagic ocean. Here only one chapter is given to phytoplankton-based systems, while most of the text is devoted to excellent analyses of major features such as marshes, mangroves and coral reefs. There is also an emphasis on the sediment communities and their microflora which play a critical role in exchange of materials across the sediment-water interface and from land to sea.

In particular, Mann focuses on general patterns of energy flow and on average conditions within each system. Although a chapter on water movements is included, there is little on the consequences for these coastal areas of the highly episodic nature of physical changes. Instead, the homeostatic properties of coastal ecosystems are a central feature of the approach used in this book. As Mann acknowledges, further work will be needed to assess these properties in the context of extremes of variability to which they are exposed.

The final chapter, "Models and Management", brings together methods of synthesizing and using ecosystem studies in the coastal zone. The author discusses several computer simulations which attempt to reconstruct the system numerically from its physical, chemical and biological components. The general conclusion is that these exercises give valuable insights, but are far from being a predictive tool for environmental managers. Mann points out that the managerially useful models, such as those for biological oxygen demand in estuaries, would be considered by many researchers as unrealistic simplifications. The broad question he raises is whether simpler holistic models without explicit formulation of organism behaviour are not merely of empirical value, but a recognition of a general feature of the hierarchies within and between

ecosystems. This question is not new, nor confined to the coastal area, but it is central to both the future research and management philosophy for this part of our environment.

Ecology of Coastal Waters combines sound descriptive chapters with proper speculative flavouring. It is aimed at advanced students and professionals, and will be useful and interesting to all concerned with the edges of the sea. □

Galileo rules, OK?

C. J. S. Clarke

Retarded Action-at-a-Distance The Change of Force with Motion By G Burniston Brown Pp 145 ISBN 0-904378-14-4 (Cortney Publications, 95-115 Windmill Road, Luton, UK 1982) £9 95

It is in the nature of science to question, to refuse to treat anything as unalterable dogma, and so there is nothing improper in questioning the correctness of Maxwellian electrodynamics, special relativity and general relativity, as does the author of this book. In their place he proposes Euclidean space and time, with Galilean relativity, combined with retarded inter-particle action at a distance using unconventional force-laws. It is a polemical book, and so one looks for a clear critique of the central philosophical and experimental points where he differs from conventional wisdom. But one looks in vain: the experimental evidence is ignored, the philosophical arguments evaded.

For example, in his theory electromagnetic interactions are linear and linked to the Euclidean geometrical relations between the particles involved, thus it is crucial that a null result be obtained for the "gravitational bending of light" experiment. And so it is astonishing that his only reference on this subject is to a 1930 article criticizing the "early claims that the effect of gravitation on light at eclipses had been proved", as if the author were unaware of the work of Counselman, Fomalont and Sramek that improved on the early eclipse observations by an order of magnitude in accuracy.

Gaia anew

J E Lovelock's *Gaia A New Look at Life on Earth* (reviewed in *Nature* 282, 154, 1979) has now appeared in a paperback edition. The book is published by Oxford University Press, price £2 95.

The crucial difficulty with any direct action theory is the explanation of radiation-reaction, as manifested in the behaviour of charged particles in accelerators. It was this difficulty that led Wheeler and Feynman to propose their time-symmetric direct action theory, explicitly rejected by the author. Yet he concerns himself almost exclusively with phenomena such as current electricity, where it is possible to avoid the problem, and nowhere gives a clear account of radiation-reaction on individual particles.

The treatment of philosophical issues is no more satisfactory. The author is proposing a Galilean structure for space-time, but without any serious philosophical justification whatever. One supposes that he holds to the Kantian view that the Euclidean nature of space is part of its *a priori* status, but Kant was writing before Poincaré, Reichenbach and Gruenbaum, and before the Eötvös-type experiments of Dicke and Braginsky on which the relativistic concept of space is nowadays based. Dr Burniston Brown is writing after these writers and experimentalists have shown that it is far from obvious that the "space" used by astronomers is necessarily Euclidean. In 1880 this book might have been a useful contribution. In 1982 it is conspicuous only by its omissions. □

C J S Clarke is a Lecturer in Mathematics at the University of York

"THE MOST COMPLETE HISTORY OF THE ATOM TO BE PUBLISHED" *Energy Daily*

The Atomic Complex

by Bertrand Goldschmidt is an accurate, complete and fascinating worldwide political history and personal memoir of nuclear energy — from the development of the bomb in World War II to today's nuclear energy complex and proliferation problems.

Goldschmidt, a leading French scientist turned international statesman, reviews half a century of political moves, counter-moves, international intrigue and manipulation. *The Atomic Complex* is a pragmatic look at the nuclear world today, carefully examining the terror nuclear weapons represent, but at the same time stressing the benefits of nuclear energy.

Principles, policies and pipelines

The great Siberian pipeline row has caught out most Western governments (and the Reagan Administration in particular). The need is for a compromise. But intellectual work is also necessary.

The quarrel between the United States and Western Europe about the Siberian pipeline is another vivid illustration that nothing so confounds international relations as incomprehension, a failure to appreciate that other parties to a dispute may also have a case. But even when the origins of such disputes are insubstantial, the consequences may be as damaging as when the conflict is about some tangible issue, say a disputed piece of territory. Already, four European companies (three French, one British) have been put on an unprecedented blacklist to which United States corporations will be forbidden to supply goods. More European companies will no doubt soon join them, for there has so far been no break in the seeming determination of Western European governments that their domestic manufacturers should honour contracts for supplying equipment for the pipeline project. But in the long run, the financial damage to the companies concerned will be negligible compared with the damage done to relations between Europe and the United States. Paradoxically, even those in the Soviet Union who may at present be delighted at the apparent discomfiture of the Atlantic alliance may in the end themselves be discomfited (Soviet readers, as important a part of any international journal's readership as any other, please note).

Responsibility

President Ronald Reagan and his advisers must shoulder the prime responsibility for incomprehension. That Mr Reagan should have turned out to be a more zealous advocate than his predecessor of the use of economic sanctions to bring political pressure on the Soviet Union is not of course surprising, for it was well advertised in advance, but even Mr Jimmy Carter followed a similar course after the appearance of Soviet forces in Afghanistan at the beginning of 1980. The US government's present calculation is that economic sanctions against the Soviet Union, and in particular the denial of specialized supplies for the Siberian pipeline, will indirectly bring about a relaxation of the martial law regulations imposed in Poland last December. The questions whether the calculation is correct, whether the United States has reason to expect Western European governments to share its conclusions and objectives — and why President Reagan appears to have passed up the opportunity to find out at the June summit meeting at Versailles — are important but do not touch the central principle. It is the same with the questions that have been raised about the wisdom of the Western European governments agreeing to buy natural gas from the Soviet Union — strategic dependence in energy supply and the provision of a steady flow of hard currency over the decades ahead (see *Nature* 22 July, p 313). What matters, and what the United States appears to be incapable of understanding, is that these arrangements were concluded during Mr Carter's presidency, were then widely regarded in a very different light and could not now be abrogated retrospectively without causing serious legal difficulties for Western European corporations and even for their governments.

Mr Reagan's government is now busily making matters worse by insisting that one of the objectives of its present policy is to demonstrate to all concerned, Europeans as well as the Soviet Union, that the United States has reassumed the leadership of the Atlantic alliance. While, after several years of US indecision, that

message would ordinarily be welcome in Western Europe, its timing and its manner are inappropriate, not to say inept. For the governments in Western Europe that Mr Reagan now wishes to have follow the United States in being tough with the Soviet Union are, like his own, governments by the grace of their electors. And it has not been forgotten in Western Europe that the long and painful decline of Chancellor Helmut Schmidt's coalition government in West Germany dates from the time when he put his political future on the line in favour of President Carter's proposal to base neutron bombs in Europe — and then found that Mr Carter had climbed down without telling him in advance. Mr Reagan's present position on the pipeline, whether justifiable or not, is bound to seem to many as a reversal of previous policies without consultation, let alone agreement, and will thus strengthen the Gallic line towards the Atlantic alliance that has been rife in Europe for decades — the view that, over the long run, the interests of the United States are unlikely always to coincide with those of Western Europe, for which reason Western Europe had better plan for self-sufficiency.

European governments, whatever their political colour, will not be able to overlook the growth of this opinion, even if it should be misconstrued, to fail to do so might be to risk electoral defeat, even replacement by gallically-inclined successors. But even governments not now at risk, or which (like the British government, with the Falklands war behind it) keenly appreciate the importance of assistance from the United States, may find it impolitic to stomach the style of leadership now on offer. Unless the quarrel about the pipeline is quickly patched up, it is not entirely far-fetched that it could mark the beginning of the end of transatlantic arrangements for the defence of Western Europe. Strange though it may seem, that would not be the unmixed benefit for the Soviet Union that it would seem at first sight to be, for there is every chance that Western Europe living more by its own devices than at present would be a more awkward, if less predictable, customer than it is now.

Retreat

Retreating from the present position will demand more diplomatic skill than either the United States or Western Europe has shown in the past few months. Although the pipeline issue has been rumbling on since the beginning of the year, neither of the parties seems to have done what prudence would have required at the Versailles meeting — insisting that it should know for sure what was in the other's mind. Instead, the official communique includes a vague reference to the need for caution in dealing with the Soviet Union, given the troubling events in Poland in previous months. President Reagan seems diffidently not to have asked for a commitment to boycott the Siberian pipeline, and the governments of Western Europe to have been content to let sleeping dogs lie. Since then, embarrassment, indolence and more recently bad temper have been substituted for rational discussion. Until the imposition in mid-August of sanctions by the United States on French pipeline suppliers, it would have sufficed that the United States should have demanded of Western Europe an account of what it planned to do to implement the loose wording of the Versailles communique. Now, with opinions on both sides hardened, the only hope for a resolution of the quarrel is that there should be a serious attempt to hammer out a policy on

economic relations with the Soviet Union on which the governments concerned can agree, or agree to disagree. The more public that process, the more easily the United States could abandon as it must its sanctions against companies in Western Europe without losing face.

Agreement is too much to ask for, but a basis for civilized disagreement should be attainable. The underlying issue is what kind of relationship should obtain between the industrialized West and the industrialized East, partners in a more vexing dispute than over a mere pipeline. A few things are agreed, at least formally: there should be negotiations on strategic arms control, and neither side will sell defence equipment to the other. Two other issues are more fuzzy: the extent to which personal freedom is subordinate to or the basis for the integrity of the state, and the part that should be played in such a tense relationship by what would otherwise be considered normal commercial and cultural relationships. Broadly speaking, the governments of West and East differ radically on the first question (which is why they are at loggerheads), but the West is divided among itself on the second. It is possible to argue that the restraint of commerce will force illiberal regimes to become more liberal, but also that the opposite is the truth. The perplexity of British governments about the encouragement of sport in the Republic of South Africa is a proof that historical precedent is not a sure guide.

In such circumstances, the only acceptable basis for an understanding between the disputants of the West is that they should all know clearly where they stand on the restraint of commerce and of cultural relations and (knowing the hazards of ballot-box democracy) should be able to lay odds about where they may stand in future. On the face of things, there is much to be said for Andrei Sakharov's position (see page 199) that the questions of strategic arms control and of human rights (the nature of democracy) should be uncoupled and that the principle should also be extended to uncouple commercial relations on non-military commodities (such as natural gas) from the issue of personal liberty. For once restraint has gone so far that the provision of pipeline equipment is not allowed, the time would soon arrive when even the sale of ostentatiously unstrategic commodities (cereals, say) to the Soviet Union would be disallowed. Paper clips could just as easily be embargoed.

Ostensibly, none of this has much to do with the scientific community, but the contrary is the truth. The tale of how Sir Humphry Davy went on a scientific jaunt (with his new bride) through mainland Europe at the height of the Napoleonic Wars is almost too well known, while the fact that Pugwash could safely meet in Warsaw this August can easily be discounted on the grounds that it is no longer in a position to risk giving offence. Protests among Australian biochemists and other professional people that the federal government should not have put last month's meeting of biochemists at Perth in hazard by denying visas to two Soviet officials travelling as scientists are more to the point, if only because they illustrate how intimately government officials rather than professionals are now involved in the judgement of what should be done. (To its credit, the Australian National Academy of Sciences has done everything that might have been expected of it to protest.)

But such issues are too important to be left to government officials. Professional people in the strict sense should have more say. Natural scientists could (and therefore should) argue that their lives would be more interesting and therefore more productive if there were less, not more restraint. Economists (regarded as scientists proper in many places) have much to say about the fructifying all-round benefits of more trade, whatever its nature or with whom. Historians (also still considered to be professional scientists in most of mainland Europe) have important information to contribute about the unfolding of enduring events. If professional people are serious in their protestations that the present world is dangerous, they would be well-advised to turn their energies from saying that nuclear war would be cataclysmic to showing how to solve the more subtle but more urgent problem of East-West relations which has so perplexed the most powerful governments in the past few months.

Doing one's thing

What do the British Association, ICSU and the Falkland Islands have in common? Distraction.

Crisis is not everybody's agenda, and the British Association for the Advancement of Science duly met last week at the University of Liverpool for its annual jamboree. To nobody's surprise after 150 similar occasions, there were few surprises. Thus Dr Beverly Halstead rehearsed his previously advertised objections to cladistics, Dr W. Eldridge (Gould's collaborator on punctuated equilibrium, and now curator of fossils at the New York Museum of Natural History) replied and the London *Times* earned a familiar rebuke from Sir Andrew Huxley for having reported the affair as if it had sprung up anew. Most of those listening to the debate, like those attending the meeting as a whole, will have found the experience rewarding (for otherwise they would not have chosen to go). The British Association itself is in a more serious dilemma: it purports to carry the message from research laboratories to the world at large (and many daily newspapers still behave as if that were the case). For next year's meeting, the association is promising that it will have forged stronger relationships with learned societies in the United Kingdom, in the hope that its message will be more pointed. (There will still, of course, be anxieties about money.) Why does not this venerable institution stick to what it does well and have the courage to let others judge whether there are wider benefits and what they are?

The meeting of the International Council of Scientific Unions (ICSU) at Cambridge (England) this week will have seemed to its participants to be in quite a different case. Should mainland China be admitted in preference to Taiwan (yes) and if so how (no terms specified in advance)? What should be done about the prospect that thoroughly international conferences will henceforth be impossible because of the assumption by governments that they should be consulted in advance? (The government of Australia last week gave the Australian delegation to the ICSU meeting terms of reference wide enough to be a basis for almost any negotiation at Cambridge, but added the proviso that in future it should have a hand in planning conferences of this kind.) And Sir John Kendrew (once secretary-general of the union) was duly appointed president for the next three years. The international union is also short of money, partly at least because it is trying to accomplish goals for which it was not created.

The Falkland Islands are in much the same case. Earlier this week in London, Lord Shackleton (truly a relative of the polar explorer) produced for the British government (and the public gaze) his latest report on the economic prospects for these recently disputed islands. (The British government seems to have gone to war earlier in the year without having read the earlier version of the report, published in 1976.) Some of the recommendations are predictable — the only usable runway on the islands, for example, should be extended to 8,500 feet, thus allowing high-performance military aircraft as well as heavy civil transports to land safely. The proposed deep-water jetty is more of a surprise, as is the proposal that the ownership of land should be transferred, as is only just, to those who work it. In present circumstance, Lord Shackleton's proposal that there should indefinitely be a military garrison on the Falklands and that there should be a development agency modestly to encourage low-technology industries (fishing, knitting and the like) will similarly not cause consternation.

Predictably what remains unsaid is that the Falkland Islands, like the British Association for the Advancement of Science and the International Council of Scientific Unions, cannot be allowed to find their own level in the scheme of things (serving the membership or making arrangements that enable science to function internationally) because of external circumstances, the recent conflict, the shortage of money and the ubiquity of political considerations respectively. Is it not high time that such institutions (even islands) were allowed to get on with what they can do, and were not expected to do what is beyond them?

US fights Canada on Videotex

Moynihan plans retaliation for Ottawa law

Washington

An international war of nerves between the Canadian government and Senator Daniel Patrick Moynihan (Democrat, New York) may break into the open in September, affecting the fates of the Canadian, British and French videotext and teletext systems now competing for a prime position in the huge US market.

When the Senate's Finance Committee meets in late September, to take up a rather parochial bill dealing with US-Canadian broadcasting relations, it could well adopt a policy that would cripple Canada's videotext system, Telidon, as a contender in the US market — thus improving the chances of Britain's Prestel and France's Antiope, which until now had seemed dim.

The *agent provocateur* is Moynihan, who announced in June that he would try to introduce a clause into the bill (S.2051) that would prevent the treatment of any monies spent by US businesses to adopt Canada's Telidon system as a business expense. Many major US news organizations, such as Time-Life Inc., are well along the road towards adopting Telidon. Moynihan's clause has been denounced by an association of 100 US companies and individuals, the Videotext-Industry Association, as "an unprecedented and unreasonable kind of trade warfare".

Moynihan's clause is intended as a stick to beat the Canadian government and make it bend on a completely different issue. Moynihan's home state of New York includes several US broadcasting stations near the Canadian boarder that derive large audiences and considerable advertising revenue from Canada. The stations have been up in arms ever since 1976, when the Canadian parliament adopted a law, known as C58, that attempted to gain "cultural sovereignty" over what is broadcast in Canada. As Canada could not legally prevent incoming broadcasts (which are picked up by cable networks), it used the only legal means at its disposal and deprived Canadian companies of the right to treat as a business expense the cost of advertising on these US stations. The stations promptly called on Washington to do something. They estimate they have lost \$20 million annually in advertising.

Thus began what is now called the "border broadcaster's war". Both President Jimmy Carter and the office of the US Special Trade Representative have criticized the Canadian action. Congressmen from states along the border

have introduced legislation depriving US companies that advertise on Canadian broadcasting stations of the right to deduct their advertising revenues. But the Senate's bill (S.2051) is an insufficient weapon: the Canadian stations stand to lose only about \$3 million in advertising revenues, compared to the \$20 million lost to US stations under the Canadian law.

Thus Moynihan has hit on Telidon as an additional means of bringing Canada to the negotiating table. Canadian engineers worked closely with AT&T, NBC Inc, RCA Corporation and others to develop the "North American Standard" as a common standard to which all videotext and teletext systems should adhere. A key element in the system is the concept for

drawing graphics that is at the heart of Telidon. AT&T's own videotext system, which is not as fully developed as Telidon, would be compatible with this standard as would the French Antiope. These and other companies have jointly protested to Moynihan, citing the "severe negative consequences on the development of electronic publishing in the United States".

So far, the Canadian government had refused to be drawn on Moynihan's proposed action against Telidon but Canada will probably protest to the State Department if and when the clause seems likely to become US law.

The gigantic Times-Mirror newspaper empire, Time-Life Inc. has also protested strongly against the Moynihan proposal

Posts and statutes change at CNRS

A close henchman of Jean-Pierre Chevènement, the highly political French minister for research and industry, is to take up the top job in the management of basic science in France — the director-generalship of the Centre National de la Recherche Scientifique (CNRS). CNRS has a budget of FF6,000 million (£500 million) and a staff of 20,000, and most French scientists aspire to be supported by it. The appointment and major reforms in the statute of CNRS were announced last week in moves described by the minister as marking a "great change" in French science.

Some people, however, fear an increase in the political control of French science, something the CNRS directorate has long resisted on the principle that scientists are the best managers of science.

Certainly, there are some grounds for concern. Last year, the then president and director-general of CNRS resigned over the issue — when the minister tried to appoint his own nominee as director of social sciences. That post remains unfilled, as Chevènement appeared (remarkably) to have misconstrued the CNRS constitution.

But the constitution is now changed, so that CNRS scientific directors appointed only on the advice of the director general, rather than on his instruction and their powers will be increased in a general devolution of power in the CNRS management.

The new appointee to the CNRS director-generalship, 43-year-old physicist Professor Pierre Papon, denies, however, that the powers of his new post will be reduced. The increase in ministerial power "is only formal" he said on Monday. In practice, there will be constant discussion between CNRS and the ministry "as always". As for the great changes, CNRS will protect basic science, said Papon, but will now take more account of national cultural, economic and social needs.

Further, the powers of the director-

general will be increased in relation to the CNRS council, which will no longer make appointments and is renamed the council of administration. Claude Fresjacques remains president of CNRS and of this reduced council. One important power remains with the council, however: deciding the budget.

It is stressed at CNRS that there was no disagreement between Chevènement and the man Papon will succeed, Professor Jean-Jacques Payan. Although only ten months in his post, Payan has been enticed to a key job at the ministry of national education — where he will be responsible

Payan — universities. Papon — science.

for universities and research. Payan's move, in fact, may help to strengthen Chevènement's hold on university research (which, except through the research councils such as CNRS, is strictly outside his control) insofar as Payan himself is a one-time Chevènement nominee (for the CNRS director-generalship).

Other reforms in CNRS announced include the establishment of new, partially elected committees to advise the scientific directors and the creation of two new scientific directorates, one for the application of CNRS results, and one for publications and popularization. The constitution is also changed to allow profitable liaisons to be made between laboratories and industry. The changes are closely in line with the "law for research" voted by the National Assembly earlier this year (*Nature* 8 July, p.110).

Robert Walgate

fearing that the clause may be more destructive of US than of Canadian economic interests.

Moynihan's staff counters that the market for videotext and teletext is still so fluid in the United States that the big customers, who plan to use these systems to bring newspapers and news services into homes within a decade, can still choose the French or British system, that under development by AT&T or some other.

The US Federal Communications Commission (FCC), which has the legal power to affect the outcome by developing standards for this new industry or by endorsing some industry-proposed standard, is standing aside. In October 1981, FCC announced that the market should decide which systems were the best. The announcement, not yet a formal notice, heartened British Videotex and Teletex of New York, the company responsible for marketing Prestel in the United States. So long as FCC does not endorse a North American standard, Prestel still has a fighting chance. Senator Moynihan's clause would give it even a better one.

Deborah Shapley

Canada and yellow rain

UN expert group asked to act

Washington

This autumn will see a test of the United Nations' ability impartially to examine allegations of Soviet-inspired use of toxin weapons in South-East Asia. The Canadian government has submitted a report to the United Nations that gives credence to the charges and explains how they could be resolved. It will be up to the Group of Experts convened by the General Assembly to recommend to the Assembly whether or not to take up the report's suggestions. So far the Group of Experts has failed to reach any conclusion. The Soviet Union has denied that there is any toxin warfare in South-East Asia.

Canada has strongly supported the extension of the Group of Experts' mandate last year when its first investigation did not decide the matter. Refugees from Laos and Kampuchea say that helicopters and fixed-wing aircraft have been spraying poisonous gas that causes death to humans, animals and plants. If this is true, the Vietnamese, who

are presumably flying the planes and helicopters, would be in violation of the 1925 Geneva Protocol prohibiting the use of poisons in warfare. If, as is suspected, the Soviet Union is the source of the toxin weapons, it is in violation of the 1972 Convention on Biological and Toxin Weapons.

Independently of its active role on the issue in the United Nations, the Canadian government commissioned its own study of the matter. In February it asked Dr H. Bruno Schiefer, chief of the toxicology group in the Western College of Veterinary Medicine at the University of Saskatchewan, to try and resolve the veracity of the charges. Dr Schiefer made a two-week visit to Thailand — neither he nor the Group of Experts were allowed into Laos or Kampuchea to check reports first-hand or take samples. Like the Group of Experts, Schiefer interviewed refugees through an interpreter and took samples from border areas near the sites of the alleged attacks.

Schiefer concluded that the events reported to have taken place at the time of the alleged attacks "cannot be explained on the basis of naturally occurring phenomena". He corroborates an assessment made by the US Department of State earlier this year that toxin warfare was indeed being conducted there (*see Nature* 25 March, p291).

Schiefer first sought to resolve an apparent inconsistency. The poisons found in border areas, the particular tricothecene mycotoxins involved, act slowly and would have to occur in massive quantities to cause human death. Yet refugees seemed to say that clouds of "yellow gas" sprayed from the air caused death immediately. After close questioning of refugees, Schiefer concluded that the human deaths were not occurring immediately but that humans, animals and plants in the vicinity were dying 10 to 14 days afterwards. This would be consistent with the level of poison reaching the ground in sprays.

Another problem has been that the tricothecene mycotoxins involved could not alone penetrate the human skin in such a fashion as to cause death. Schiefer began searching for possible agents that might be combined with the tricothecene to facilitate entry through the human skin. Because some of the refugees reported a garlic-like smell after the attacks, Schiefer suspects that dimethyl sulphoxide (DMSO) could be such an agent. The report suggests future field searches for DMSO and other possible agents.

The report also urges that a search should be made for the only known mycotoxin that could kill through ingestion, macrocyclic tricothecene, which thus would not need any additional agent to penetrate the skin.

Communication without compatibility

None of the six main videotex standards is fully compatible with any other. Each offers a different solution to the central problem of balancing quality of display against the cost of the terminal.

At the cheap end of the scale are the systems with "alpha-mosaic" graphics, producing pictures on the screen with a crude building-block appearance. The memory of alpha-mosaic terminals stores a limited repertoire of basic mosaic shapes, from which an incoming byte of data can extract a particular shape and place it in a particular slot on the screen. The result, although inelegant, is economic in the use of memory and transmission bandwidth. But the description of information in the database is terminal-dependent.

"Alpha-geometric" systems specify pictures in terms of basic geometric figures and coordinates of a point on the screen. Almost any shape can be created and placed anywhere on the screen, while picture descriptions are not generally terminal-dependent. But greater memory and processor requirements raise the cost of such terminals.

The leading videotex systems have the following characteristics:

● **Prestel:** An alpha-mosaic standard established in 1974 by the British Post Office (now British Telecom) in cooperation with the broadcasting authorities BBC and IBA. Internationally, there are more Prestel-type terminals than others. Extended graphics capability is being developed.

● **Antiope:** The alpha-mosaic standard developed by the French tele-

communications and broadcast authorities (DGT and TDF).

● **Telidon:** The first alpha-geometric standard (produced by the Canadian Department of Communications) has attracted much attention for its superior display capability.

● **32×16 US alpha-mosaic:** The central characteristic of this system — 16 lines of 32 characters — is based on the low-cost Motorola VDG microchip. It has been adopted by US cable television and microprocessor manufacturers.

● **CEPT:** An attempt by the Association of European Telecommunications Administrations to establish a unified European alpha-mosaic standard. The standard can interpret data according to either the Prestel or the Antiope schemes, depending on the terminal.

● **PLP:** AT&T's Presentation Level Protocol is not a standard in itself but is a vast package of options, from which AT&T will select a subset to be included in a terminal for mass production. The range of capability offered is so great that a comprehensive terminal would be of prohibitive cost. The importance of PLP is its flexibility and AT&T's formidable powers for production and marketing. Other suppliers are willing to modify their standards to be compatible with PLP. The CEPT standard is compatible with the PLP alpha-mosaic subset, but is restrained from change because of the many videotex and teletex sets already in use in Europe. Discussions with AT&T to modify its alpha-mosaic subset may prevent a permanent split between US and European standards. **Bronwen Maddox**

Schiefer also found that tricothecene mycotoxins do not occur naturally in the environment in the region — as they do in other places (such as Saskatchewan). Nor did he find evidence of the human illnesses that are associated with naturally-occurring tricothecene mycotoxins. His report recommends more systematic questioning of refugees so that a proper epidemiological survey can be made.

The mycotoxins in question are toxin weapons, whose production, development, stockpiling and transfer is forbidden by the 1972 Convention. Use of the weapons in warfare is prohibited by the 1925 Geneva Protocol. There has been some confusion about whether to count the

mycotoxins as chemical or biological weapons because although chemicals they are the products of living fungi.

Schiefer's report suggests that the agent involved may be not only the pure chemical but the chemical and fungus mashed together. It recommends that future field work should look for evidence of the fungi that produce the poisons.

The Canadian government has not formally endorsed Schiefer's report but has forwarded it to the Group of Experts. Its own study of the matter will continue, it says. The Group of Experts is due to report to the next General Assembly, which opens in mid-October and will stay in session about six weeks.

Deborah Shapley

Sakharov note makes waves

Pugwash survives Warsaw

Last month's Pugwash Conference in Warsaw — the thirty-second in the twenty-five year history of the Pugwash movement — stressed, once again, the special responsibility of scientists to help "devise means to limit and eventually reverse" the arms race, and their "major responsibility" for disseminating knowledge about the meaning and implication of their work. As is customary, the conference concentrated on major issues of arms proliferation and control, destabilizing factors such as the possible use of food and energy strategies for political means and current or recent world conflicts — Namibia, the Falklands, Iraq-Iran, Afghanistan and Lebanon. But what the council's concluding statement called "the deteriorating international climate" was reflected in two topics which did not appear on the official agenda — a letter to the Pugwash movement from Academician Andrei Sakharov and the meeting of council members with General Jaruzelski.

The Sakharov letter was not originally intended for the Warsaw meeting but for the Pugwash Silver Jubilee Conference in Canada earlier this year. It seems to have been delayed in transmission, however, and shortly before the Warsaw meeting came into the hands of one of the intending participants, Dr Joel Primack from the University of California.

Under Pugwash procedure, because Sakharov had not himself been invited to the conference, the letter could only be circulated as a background document. Not surprisingly, there was considerable Soviet opposition — one Russian proclaiming that since twenty million Soviet citizens had died during the Second World War, it was inappropriate for "anti-Soviet propaganda" to be distributed at a Pugwash meeting. Finally, however, normal procedure prevailed.

The Sakharov letter in fact contained little new. It censured the negative stance taken by Soviet delegations at international meetings where "in all discussions of critical problems, they always behave as

well-disciplined functionaries of one gigantic bureaucratic machine".

As in several previous statements, Sakharov gave "absolute priority" to the achievement of international security and disarmament. In spite of his known opinion that there should be no absolute linkage between disarmament and human rights, he also appealed to the participants to speak out in defence of prisoners of conscience in the Soviet Union.

While generally sympathetic, the conference could not agree with Sakharov's view that "the West would be unable to withstand the forces of the USSR and its camp if nuclear and thermonuclear weapons were excluded from the balance". Rather, the conference concluded, the concept that the Warsaw Pact conventional forces are significantly more powerful than those of NATO needs "searching reexamination".

The problem of linkage seems to have underlain many of the doubts expressed by participants about the meeting of the Pugwash Council with General Jaruzelski but meetings with the head of state or government of the host country are a Pugwash tradition.

Pugwash participants say they put a number of searching questions to the general on the implications of martial law, the future of Solidarity and the fate of internees, and that he predictably replied that the present "state of war" was necessary to defend the state and economy from anarchy, but that "a number of democratically orientated social, political and economic mechanisms" had nevertheless arisen.

Even so, some participants felt that the very fact of the meeting might in some sense be interpreted as conferring a kind of approval on the current military regime. Jaruzelski, himself, however, carefully avoided any such claim, saying only that the choice of Warsaw for the Pugwash meeting was an expression of respect for the Polish nation, and of trust in its wisdom.

Vera Rich

European community research

Spending money

Brussels

The brief Belgian summer has not distracted officials at the European Commission from putting together plans for the new European science strategy agreed at the ministerial meeting on 30 June. Three papers have been presented to the Council of Ministers, EEC's decision-making body, covering the reform of the research and development programme of the joint research centres, the preliminary phase of the Esprit programme on information technologies and the first phase, for 1983, of the long-term plan to stimulate the scientific and technical potential of the European Community.

The last of these projects, however tentative, is the most interesting. The Commission is proposing that the Community should spend \$5 million to stimulate research in seven selected fields, thus paving the way for spending on a larger scale in the period 1984-87. For next year, the plan is that funds should be spent on a handful of fashionable fields of enquiry — new applications of cell and molecular biology, composite materials, mathematical analysis applied to optical problems, the behaviour of materials in the presence of combustion, non-destructive testing, interface phenomena and transitory effects in climatology. Information technology is already catered for by the Esprit programme.

If the Commission's proposals are accepted by the Council of Ministers, the research ministers at their meeting arranged for 30 November will invite applications for research funds in respect of both the pilot programme for research and development and for Esprit.

One of the attractive features of the pilot programme is that funds will be available for multi-national projects, including seminars and workshops, as well as for the travel and research expenses of scientists working at foreign laboratories.

The research ministers are unlikely to be as pleased with the Commission's paper on the joint research centres, the latest revision of the rolling three-year programme. The rising cost of the Super-Sara project on reactor safety is the perennial stumbling-block, especially for those governments that were dubious about the project at the beginning. The Commission now argues that work on this project should be pushed ahead so that the past investment in it will at least yield some information in time for it to be used in the design of light-water reactors, but it is not yet clear whether these arguments will prevail. For the rest, however, the Commission has proposed that the work of the four joint centres should be brought more into line with the new framework proposed for the general support of research and development.

Jasper Becker

Ariane in space

What next?

Last week's failure of the fifth Ariane flight is bound to have repercussions on the launcher's commercial prospects. But officials at the European Space Agency (ESA) are still hopeful that the fault that caused the failure in the rocket's third stage will prove to be no more than a manufacturing error, thus reassuring customers of Ariane's basic soundness. Three previous successful flights are taken as testimony that the fault probably does not lie with the design.

ESA is keen to point out that the rocket's first and second stages worked perfectly. But the third stage, which was carrying two satellites into geostationary transfer orbit, suddenly lost power after about 4 seconds and brought the satellites back down to Earth. A preliminary analysis of telemetry data recorded at a station in north-east Brazil has revealed a sudden failure in a gear controlling the flow of cryogenic propellant from the liquid oxygen and liquid hydrogen pumps. Nobody yet knows, however, precisely what went wrong with the gear.

Whether the failure was due to a simple error or to a more ominous design fault, sorting it out is bound to delay the future Ariane launch programme. A lengthy delay could postpone the launch of Exosat, ESA's X-ray astronomy observatory, from its scheduled date of next November to June or July next year. Exosat can only be launched during specific launch windows around December and midsummer.

Although a delay to Exosat could upset Europe's hard-done-by X-ray astronomers, ESA is bound to be more worried about the effects of delay and uncertainty over Ariane's reliability on the launcher's potential commercial customers. Intelsat, the international owner of the Intelsat series of telecommunications satellites, for

example, is due to launch three of the Intelsat 5 series on Ariane next year. Although the organization has made little response yet to last week's failure it will be watching the next Ariane launch keenly before making any firm commitments.

Meanwhile, ESA is having to decide how to make amends for Marecs B and Sirio 2, the two satellites lost last week. Sirio 2, a telecommunications satellite of primarily Italian design was uninsured, but the insurance money from Marecs B could be used to assemble quickly Marecs C, possibly for launch at the end of 1983 or the beginning of 1984. Inmarsat, the International Maritime Satellite Organization which had planned to lease channels on Marecs B for maritime communications in the Pacific, says that it can continue its present service in the area with the US Marisat satellite. But it is likely to take up ESA's offer to assemble and launch as quickly as possible the Marecs C replacement.

Amendments to the launch programme could delay the transition of the Ariane programme from ESA's control to that of Arianespace arranged before last week for July or August next year. Arianespace seems likely to take longer than expected before earning money. The company's prospects also seem to depend more than it must have hoped on the success or otherwise of the space shuttle, due to make its fifth (and first operational) flight in November.

Judy Redfearn

Spina bifida

Trials ahead

The Medical Research Council (MRC) is soon to start trials to investigate the role of folic acid and other multivitamin supplements in the prevention of neural tube defects (NTD). The programme is controversial because of its ethical implications. Women invited to participate will already have conceived one spina bifida baby and are therefore at risk of conceiving another. In order to understand the effects of dietary supplements, women in the control group will not be given multivitamin and folate supplements.

The government is to give £300,000 for the first three years of the trials. Although many scientists and doctors believe that multivitamin supplementation is important in the reduction of NTD, MRC says that new trials are necessary because previous experiments have not provided strong enough evidence for such a link. Experiments on folate and multivitamin supplementation at the Universities of Cardiff and Leeds are considered not to have been properly randomized. The women who participated were mainly from the middle classes and therefore at lower risk anyway.

The MRC programme will involve 3,000 women at 20 centres. There will also be centres in Israel and Australia. The women

will be offered full antenatal screening facilities and the centres will have to be approved by local ethical councils. The volunteers, who are planning a pregnancy (pills are taken before and after conception), will be randomized and divided into four groups. The first will receive pills containing minerals plus multivitamins, the second minerals, multivitamins and folate, the third minerals and folate and the control group minerals only. This design will permit a comparison between the multivitamin effect and the folic acid effect.

The National Childbirth Trust has written to the Minister of Health, Mr Kenneth Clarke, expressing its worries about the trials. It says that there is already sufficient evidence to link folic acid deficiency with spina bifida and point out that the women participants will have a one in four chance of being in the control group and therefore at risk. In Britain one in 20 women who have already conceived an NTD baby conceive another.

Ethical worries about the trial's implications hang on how well the women will be briefed. The Association of Spina Bifida and Hydrocephalus (ASBAH) agrees that there is a need for more scientific evidence and that this cannot be done without further trials. Its support is qualified, however, by the proviso that the participants must be adequately briefed. At present MRC decides what information is given to women volunteers.

Dr Nicholas Wald of the Radcliffe Infirmary in Oxford, who is to coordinate the trials, stresses that the women will be invited to participate. But he points out that even if they were not fully briefed the trials would not necessarily be unethical. He argues that the trial is ethical primarily because there is a broad balance between the likely good of the treatment and the possible harm.

No one is willing to be explicit about what volunteers will be told. While women in the control group will not receive multivitamin or folate supplements, it should however be pointed out that such supplements would not necessarily be recommended by a general practitioner or by ASBAH in any case. ASBAH hopes that the MRC trials will establish what dietary advice should be given to women at risk who plan to become pregnant again.

Jane Wynn

Helsinki agreement

Monitoring stops

The formal disbanding, last week, of the Moscow "Helsinki Monitoring Group" is little more than an acknowledgement of a *fait accompli*. Since its foundation, six years ago, to monitor Soviet observance of the Helsinki Accords, the group has been subject to ever-increasing official pressure. In 1978, its founder and original chairman, Dr Yuri Orlov the physicist, was sentenced

to seven years in a labour camp, plus five years Siberian exile, for his part in the group's activities. Since Dr Orlov's conviction the active membership of the group has been whittled down by successive arrests to, effectively, two persons, Elena Bonner, the wife of Academician Andrei Sakharov, and Sofia Kallistratova, an elderly lawyer. It was apparently an official warning to Mrs Kallistratova last week that she might soon be arrested and charged with anti-Soviet activities that led to the disbanding.

The Moscow Helsinki group has not been the only victim of repression. Other Helsinki groups throughout the Soviet Union, and in particular the Ukrainian group founded by Mykola Rudenko the science fiction writer, have been similarly obliterated by the imprisonment of their members. So has the Moscow "Working Group for the Investigation of the Misuse of Psychiatry for Political Purposes". The founder members of SMOT, the "Inter-professional Free Trade Union", have all been either taken into custody or expelled from the Soviet Union. Since the arrest of Dr Viktor Brailovskii on the opening day of the Madrid "Helsinki Review" conference in November 1980, the Moscow Sunday Seminar for refusenik scientists has been able to meet only on very rare occasions, and regular participants have been subjected to harassment. Brailovskii himself is now eligible for early release from his exile in Beineu (Kazakhstan), but has so far been unable to obtain the necessary character reference from the local authorities, which, it is understood, want specific authorization from Moscow.

Some forms of grass-roots dissent do seem to have survived, however. Mrs Albina Yakoreva, a computer specialist and founder member of SMOT, who was put on a plane to Vienna last month, reported that the free trade union movement has decentralized, but that at least twenty-one grass-roots branches are active, their main object now being the building up of a climate of opinion that will accept such fundamental democratic concepts as worker self-management. In Byelorussia, which was relatively passive during the upsurge of dissent of the early 1970s, underground initiatives protesting against the russification of Byelorussian culture have been reported. The three Baltic republics, Lithuania, Latvia and Estonia, which have developed their own traditions of dissent (the *Chronicle of the Lithuanian Catholic Church* has long been one of the most prestigious underground Soviet journals, while Estonia has staged protest marches and token strikes) have, in the past year, begun to coordinate their efforts on fundamental issues. Their most significant effort so far is a letter to the governments of the Nordic and Baltic countries expressing their support for the proposed Nordic nuclear-free zone, but urging that the ban be extended to the relevant areas of the Soviet Union.

Vera Rich

Nuclear waste reprocessing

Germans divide

Heidelberg

The reprocessing of nuclear waste has predictably become an issue in the Hesse and Bavaria elections, now in full swing. The Social Democrats, the major partners in the Bonn coalition with the Free Democrats but fighting separately in the elections for the *Länder* governments, shoulder the chief responsibility for having declared that each *Land* includes a candidate site. The Free Democrats, party to these decisions but united electorally with the more powerful Christian Democrats, are more or less immune from the attacks with which the "Greens" (the environmentalist party) threaten to enliven the elections.

The 14 nuclear power plants in West Germany now produce some 350 tonnes of spent fuel-rods a year. By 1990, 25 power plants will be producing 750 tonnes a year. Under contracts with the French state-controlled Cogema, the rods will be reprocessed at the Cap de la Hague plant in Normandy until 1985, after which the outlook is unclear. Pending the completion of a second 800 tonne per year unit at Cap de la Hague, West Germany will in any case have to take back the highly reactive waste

and put it somewhere.

At present, Cap de la Hague and Sellafield (as Windscale is now called) are the only two commercial reprocessing plants functioning, but there is a chance that the smaller plant at Mol in Belgium may reopen soon (see *Nature* 26 August, p 783). Worldwide, however, there is a desperate shortage of reprocessing facilities, with 200 nuclear power reactors operating and 150 under construction. Only the US interdiction of the reprocessing of spent fuel bridges the gap.

In West Germany, after the abandonment last year of the plan for a 1,400-tonne reprocessing plant at Gorleben in Lower Saxony for political reasons and after massive environmentalist protest, the industry-run organization responsible for reprocessing is considering three 350-tonne per year sites at Frankenberg (Hesse), Schwandorf (Bavaria) and Kaisersesch (Rheinland-Pfalz).

The final storage of wastes, however, remains the responsibility of the federal government. Geologists estimate that salt deposits underlie about a quarter of Northern Europe and in spite of protests and a recent controversial study which revealed unexpected depths of erosion of the salt dome during the last ice age, investigations continue.

Sarah Toozee

Biotechnology briefs

The Cetus Corporation announced last week the first lay-offs in its history and a substantial refocusing of its research and development on projects that would be likely to pay off in the short term. Forty employees have been laid off, and projects dealing with the production of high-purity fructose and energy and chemical processing have been stopped. Cetus raised a record \$107 million with its public offering of shares in March 1981, but Standard Oil of California, a major shareholder, has declined to continue supporting fructose work at the company.

Another biotechnology company with ambitions in the artificial sweetener field is about to make a public stock offering. The Genex Corporation of Rockville, Maryland, is expected to offer 2.5 million shares in late September or early October, which could raise as much as \$33 million according to documents that Genex has filed with the US Securities and Exchange Commission (SEC). Genex already has a production plant for L-aspartic acid, which is used in the production of aspartame, a sweetener marketed by the Searle Corporation that was recently approved by the US Food and Drug Administration. Genex is also interested in genetically-engineered production of calf rennin, bovine, porcine and ovine animal growth hormones and various industrial chemicals. The company is 45 per cent owned by the Kopper Co. Inc. of

Pittsburgh, a major chemical concern. The company, which is one of the largest genetic engineering companies in the United States, has grown steadily through contract research, the income from which rose from zero in 1977 to \$3.9 million in 1981.

Eli Lilly and Co. of Indianapolis is expected to announce later in the month the availability of the first genetically-engineered product for human use, human insulin. The work has been carried out by Genentech Corporation of South San Francisco.

Meanwhile, Amos Corporation, also of South San Francisco, a company founded in June 1980 by Brian T. Sheehan, formerly of Genentech, has filed for bankruptcy in the San Francisco courts. Sheehan says that this will enable the company to reorganize and that several investors are interested in its potential.

Another Canadian entry into the biotechnology field is Allelix of Mississauga, Ontario, whose scientific director, Derek C. Burke, is leaving the University of Warwick in the United Kingdom to work full-time for the company. Allelix is a joint venture between the Canada Development Corporation, John Labatt Limited and the province of Ontario. Burke says that the assurance of Can\$100 million over the next ten years will prevent the company from having to "panic" in the quest for short-term genetically-engineered products.

Deborah Shapley

CORRESPONDENCE

No to quangos

SIR — Your leading article in *Nature* of 5 August ("James Watt and biotechnology", p 501) asks some important questions, which you imply that only the government can answer. The difference between James Watt's doings and ours is that he was free from committees and we are not. I agree that to go back to James Watt would do no harm, provided that in going back we dismantle the bureaucratic structure that strangles our communications. Mr G H Fairtlough may understand the links between the Medical Research Council and the British Technology Group (and the National Enterprise Board and National Research and Development Corporation) and Celltech, but few others do. Things would work so much better without these complicated bureaucracies and we and Mr Fairtlough would be free to compete or collaborate with each other, and free to collaborate with the research scientists.

You ask how the government can give British industry a sporting chance of survival. The answer (towards which the present government is working) is to leave it alone. Take the committees and the quangos (and the formal channel of communication between the Department of Industry and the University Grants Committee) off our backs.

Cold war

SIR — I am afraid that E G Dimond's suggestion to exchange ¼ million young people between the United States and the Soviet Union as an alternative to arms race (*Nature* 15 July, p 220) would be more unacceptable to the Soviet Union than a tenfold increase in arms buildup by the United States. Why? It would be labelled as a "philistine ploy (1) for mass infiltration of the Soviet Union by CIA agents and (2) for infecting Soviet youth with decadent bourgeois ideology to use them later as a Trojan horse to disrupt the fabric of the socialist society". This is the essence of the tragedy why every effort to reduce tensions, promote detente and so on must inevitably end in deadlock.

Ontario, Canada

China syndrome

SIR — In *Nature* of 19 August (p 746) you published a paper entitled "Age of the Lufeng, China, hominoid locality". One of the authors, Qi Guo-qin, appears on the contents page as Q Guo-qin, which wrongly assumes Guo-qin to be the surname, and is a common mistake among Westerners.

The convention in Chinese names places the surname first, followed by the given names, which are usually hyphenated. The author is therefore Mr Qi not Mr Guo-qin. The Chinese tend to use their names in full, and the shortened form is made by dropping the given names for well known people, as in "Chairman Mao".

There is, however, a tendency among Chinese exposed to the West to adopt our convention and place the initials of their given names before their family name. Perhaps they have become fed up with our getting their names mixed!

As scientists, the Chinese name convention should not strike us as odd — it is, after all, the same as the Linnean nomenclature!

J A IRVING

Dulwich, London, UK

Scrapie a "gene"?

SIR — In *News and Views*¹ R H Kimberlin commented on the recent suggestion by Stanley B Prusiner of the University of California, San Francisco, that the scrapie agent is a novel proteinaceous infectious particle².

The search for the scrapie virus proposed by Cuille and Chelle in 1938³, has been continuous. An early trickle of papers became a torrent when Chandler transmitted the disease to mice in 1961⁴. There have been so many variations on a virus theme that the virus hypothesis now lacks absolutely nothing, except a virus. One response to this impasse has been to call the virus "unconventional"⁵, an ingenious solution, for is not a square an unconventional circle?

In pursuing our suggestion in 1967 that the scrapie agent might be a small protein⁶, my colleagues and I applied fractionation procedures to scrapie tissues. Every experiment included control inocula of normal tissue treated precisely as the scrapie tissue, and diagnosis of scrapie was rigidly based on the presence of characteristic histological lesions in the brain⁷. These technical points are emphasized for two reasons. First, because few other investigators of the disease have used normal tissue controls in more than the occasional experiment, and very few have examined histologically the brain of every animal in every experiment, whether or not it showed clinical evidence of scrapie, this latter procedure is important in detecting scrapie agent in high dilution, or in unexpected circumstances. Second, because use of this experimental routine may explain why we apparently detected scrapie agent in tissues of some non-scrapie animals.

Our findings were published in *Nature* in 1968⁸. In brief, in over 150 experiments scrapie did not occur in any of 2,640 mice injected with unfractionated tissue from normal sheep, goats or mice (an observation matching that of many other investigators). By contrast, scrapie occurred occasionally, and unpredictably, in mice injected with fractionated tissue from non-scrapie animals. The possibility existed, therefore, that fractionation had released a scrapie-producing factor from non-scrapie tissue.

The obvious interpretation of our findings was that normal tissue had been contaminated with scrapie. To examine this criticism, we carried out further experiments in which attempts were made purposely to contaminate normal tissue inocula. By using unwashed glassware etc. we certainly produced some contamination, but the distribution of scrapie was different from that observed after injection of fractionated normal tissue⁹.

If, for a moment, it be accepted that we did

indeed detect scrapie agent in normal tissue, an explanation can be offered for the apparent enigma of replication without nucleic acid that faced us initially, and now faces Prusiner. The agent may not, in fact, replicate as the disease progresses, instead — as we suggested in 1968 — replication may be simulated by an unmasking process of a particle already present. Again, if scrapie agent were a component of normal tissue, there would be a simple explanation for the widely observed but obscure phenomenon that the scrapie agent does not apparently stimulate antibody. If the agent were "self" no antibody would be expected.

In recent years, research on scrapie in sheep has largely been bypassed in favour of the experimentally-produced disease in laboratory animals, for the obvious reason that few laboratories are equipped to handle large numbers of sheep. In consequence, it is not widely recollected that many outbreaks of naturally-occurring scrapie in sheep have been associated with close mating to improve agriculturally desirable breed characteristics¹⁰. In 1974 I reported the apparently spontaneous occurrence of scrapie in sheep selectively bred, for high susceptibility to experimental scrapie¹¹. The significance of genetic make-up in susceptibility to scrapie in sheep is beyond dispute (for example ref. 12).

It may not be far-fetched, therefore, to suggest that the scrapie agent is an inhibited particle in normal tissue, released genetically in the naturally-occurring disease in sheep.

To the point

SIR — Having read Cedric A B Smith's letter proposing a new system for representing numbers (*Nature* 12 August, p 600), I am afraid that it cannot go unchallenged. He not only suggests a totally confusing system of numbers and letters, but goes on to contradict himself.

He states "0 700 means exactly the same as 7", but is wrong since 7 is correct to one decimal place and 0 700 is correct to three places. And surely "7" can be easily confused with "7" — referring back to an earlier paragraph in his letter "what makes it worse is that especially in handwriting (and sometimes also in print) not only may dots and commas be difficult to distinguish reliably but also they may be so faint as to escape notice altogether".

NEWS AND VIEWS

The unacceptable face of Minoan Crete?

from Keith Branigan

THE Minoans were a civilized people, by soon after 2000 BC they were living in spacious houses with bathrooms, toilets and drains, and they decorated their living rooms with colourful frescoes depicting the birds, animals and fish which inhabited their beautiful island and the seas around it. Only the legend of the Minotaur, half man, half bull, which annually devoured twelve Athenian youths sent as tribute to King Minos, has cast a shadow on this idyllic scene — until the summer of 1979 when two dramatic discoveries were made in excavations only a few miles apart in central Crete.

At Knossos, the home of the Minotaur, the butchered remains of two young lads were found in a basement room of a Minoan house. Careful study of the bones suggested that cannibalism provided the only satisfactory explanation of all the evidence. Meanwhile, at Arkhanes, less than 10 km to the south, below the fallen walls of a Minoan temple destroyed by earthquake at about 1700 BC, the skeleton of a boy aged about 18 years was found sprawled across an altar, a bronze knife lying on the body. Again, a careful examination of all the evidence led the excavators to the inescapable conclusion that here was a Minoan human sacrifice. These two remarkable discoveries have naturally attracted a great deal of attention and comment, and alternative explanations to cannibalism and sacrifice have been offered, but do the alternatives fit the observed facts?

Details of the Arkhanes temple were published by S. Elliott in 1980 (*The Athenian*, 22 March 1980), with extensive quotes from an interview with the excavators, I. and E. Sakellarakis. Altogether four skeletons were found in the temple: one, a man, in the antechamber, and three (including the sacrificial victim) in the western of the three cult chambers. The other two skeletons in this room were those of a woman, lying face down and legs splayed, and of a man, fallen on his back and with his arms raised to his chest. These three skeletons are thought to be the remains of people (priests?) struck down in the temple at the time of its destruction by a major earthquake, which is well evidenced elsewhere in central Crete around 1700 BC. The fourth victim is thought to have died in

a different manner for four reasons.

First, unlike the others, he lay not on the floor but on a stone platform or altar. Second, he was not spreadeagled like the others but lay on his side with his legs tucked tightly up against the body — an unusual position suggestive perhaps of his being trussed up, but certainly not the position of someone caught by falling masonry or timber while trying to escape the building. Third, the ceremonial bronze dagger lying across his body is suggestive of sacrificial activity. Finally, the bones on the lower side of the body were stained a much darker colour than those on the upper side, and it has been suggested that this preserved traces of the manner in which the man died — from a severed artery on his left side, through which the blood drained, first from his upper right side, and eventually from his left side.

The collective evidence is impressive but not incontrovertible. In particular, pathologists in this country are unconvinced by the differential discoloration of the bones, which cannot be ascribed to the position of any supposed wound. The sacrificial weapon, too, presents some difficulties because it is not a dagger but a spearhead, and although it could be used to kill someone, it would be a cumbersome implement to use for sacrifice, particularly in the manner suggested — piercing the carotid artery of a person lying on their side on a raised altar. It might also be argued that the body fell, rather than lay, on the altar or platform where it was found. Only the position of the body is difficult to reconcile with this person being a fourth victim of the earthquake rather than of a priest's sacrificial knife, and until we have definitive reports with photographs of that position, we cannot be certain how critical to the interpretation the position of the skeleton really is. At present, the case for human sacrifice at Arkhanes has to remain 'unproven'.

The evidence from Knossos is well documented in articles and photographs published by the excavator, Peter Warren [in *Sanctuaries and Cults in the Aegean Bronze Age* (eds Hagg, R. & Marinatos,

N) 155, 1981, *Archaeological Reports for 1980–81*, 73, 1981]. A small basement room contained a deposit dating from about 1500–1450 BC, amongst which were 300 fragments of human bone. On analysis, these proved to be the remains of two boys, aged 8 and about 11 years respectively. Although examination of the skulls and bones suggested both children were in good health at the time of death, it also revealed 27 bones on which there were clear knife marks, several of them well away from the ends of bones. The bones were subjected to microscopic examination and it was concluded that the marks had been made by repeated cutting or sawing (possibly with a sharp obsidian blade rather than a bronze knife) and there was no evidence for either chopping the bones or for scraping the bones longitudinally.

The discovery of these gruesome remains in the basement of a house raises three obvious possibilities. The first is that the bodies result from an undiscovered crime. This proposition can be repudiated by observing the nature and position of the cut marks. None results from chopping or slashing, none results from blows struck with a heavy implement. Apart from marks on the torso, there are also cut marks on the legs and arms, which are difficult to explain in terms of murder wounds. Most significant, however, are the multiple cut marks at a single point — one clavicle, for example, has five marks criss-crossing each other at one point, and another three 1 cm away, these must represent repeated and careful cutting or sawing rather than eight very precisely aimed blows on the single collar bone. A second explanation is that we have in this basement the remains of two secondary burials — that is, the bones removed from an initial burial place for burial elsewhere or perhaps for use in ritual. Secondary burial was certainly practised in Crete, but there are no other examples of children being subject to this treatment, and such evidence as we have for the practice is found, not surprisingly, in Minoan cemeteries, not in town houses. In any case, how does secondary burial explain the cut marks?

Warren plumps, somewhat unwillingly, for the third possibility — that we have the first evidence of Minoan cannibalism. He argues persuasively that the only explanation consistent with the nature and

Keith Branigan is in the Department of Prehistory and Archaeology, University of Sheffield, Sheffield S10 2TN

position of the cut marks is that flesh was being cut from the bodies, and although in this case it cannot be demonstrated, the likelihood is that the flesh would be eaten. There are some further clues which support the proposal. For example, among the childrens' bones there were also some sheep bones, including a third cervical vertebra bearing cut marks consistent with the sheep having had its throat cut. In a room across the corridor from the childrens' bones, a storage jar was found containing burnt earth, snails and more childrens' bones, including one with cut marks. Are these too food remains? The ritual nature of the deposit in this second room is undoubted, with a remarkable collection of miniature vases of various shapes, each with a small hole perforating their base — typical libation vessels. Certainly, if we have evidence for cannibalism, we should look for a ritual setting (see, for example, Harris, M. *Cannibals and Kings*, 1978), whatever the real reason for the eating of human flesh may have been.

There are, however, some unusual features of the discovery which ritual cannibalism cannot explain. The first is the incompleteness of the skeletons, neither skeleton was anywhere near entire and, in particular, in neither case was there evidence for the lower legs. If the bodies had flesh removed for eating, obviously the bodies must have been newly dead, the absence of substantial parts of the skeletons cannot be explained by advanced decomposition and disarticulation. The bodies must have been slaughtered and butchered elsewhere, with only parts of the bodies being brought here, or, the butchering was done here and the missing parts removed to other places. Such events are possible, but they raise many new questions if we accept them. Second, some of the bones bearing cut marks come from parts of the body unlikely to have been eaten. Thus, all three shoulder blades, one of the two collar bones and two of the jaw bones show cut marks. If we recall that the evidence of the marks clearly points to cutting or sawing rather than chopping, and that we are therefore thinking not of butchery but of removing meat from the bone, then it is difficult to believe that in these instances we are looking at evidence for cannibalism, this is particularly true of the jaw bones.

The most economical explanation of all the observed facts that can at present be offered is that we have here evidence for post-funerary ritual involving human bones, that is, that the bones had been removed from a primary burial area and were being used in, or prepared for use in, a further ritual. The removal of bones from funerary contexts for further ritual use is attested elsewhere in prehistory (Piggott, S. *The West Kennet Long Barrow*) and there are hints of this activity in Crete by the third millennium BC (Blackman *Kretika Chronika*, 199, 1973). In particular,

Blackman refers to bones found at the Aya Kyriaki tholos tomb (*Annual of the British School at Athens*, 77, in the press) which were clearly and cleanly cut through at both ends. The cutting or sawing marks on the bones from Knossos could be traces of similar activity, although none of the bones

found in the basement has been completely cut through.

On the evidence from Knossos, we cannot assert that the Minoans did not practise human sacrifice or cannibalism, but the onus of proof must still be with those who believe that they did. □

Of cannibals and kin

from J S Jones

THERE has grown up in biology the comforting supposition that nature is not really red in tooth and claw, that animals behave, in general, in an altruistic or at least a polite fashion to other members of their own species, and that animals belonging to the same species rarely do serious damage to each other. Just how far this is from the truth is revealed in a recent account of cannibalism in natural populations¹.

Cannibalism has been recorded in more than 1,300 species, and is often the primary cause of mortality. Ninety per cent of fish fry may be eaten by conspecifics, three-quarters of crow eggs and nestlings cannibalized by adults, and a quarter of all lion cubs killed and eaten by older animals. In viviparous salamanders, a few young develop teeth which they use, while still unborn, to devour their less well-endowed sibs, and adult hyaenas often eat the corpses of others which they have killed in territorial battles. The female of most species is more cannibalistic than the male. The flesh of one's own species may be a major source of food, even in man — where anthropophagy has been recorded in some sixty cultures — human flesh was sometimes the second most important item of dietary protein. Some animals are particularly enthusiastic cannibals. Walleye fish, *Stizostedion*, eat each other 'tail first', and chains of up to four fish engaged in simultaneous cannibalism have been seen².

How can this apparently unadaptive behaviour evolve? The answer is no doubt complex and involves a variety of selective forces which differ from case to case. The individual benefits are obvious enough, for a cannibal not only obtains food but also reduces the competition. In ground squirrels, *Spermophilus beldingi*, for example, infanticide by unmated females leads to previously occupied nest burrows becoming available³. There may also be population benefits as cannibalism enables populations of desert scorpions and other animals to persist when food is short in a fluctuating environment⁴. However, the most interesting aspect of cannibalism is the insight it may give into evolution by kin selection.

It is often claimed that the behaviour of

J S Jones is in the Department of Genetics and Biometry, University College London.

animals towards other members of their own species is influenced by their degree of genetic relatedness. Altruistic behaviour, in which one individual decreases his own fitness in order to increase that of others, is believed to be particularly likely to occur when donor and recipient have a high proportion of their genes in common. Unfortunately, it is usually difficult to identify a particular behaviour as altruistic, and impossible to assess the costs and benefits to the individuals involved in the interaction. Cannibalism epitomizes selfishness. It is hence the converse of altruism, and many prove a better test of the theory of kin selection, as it is easier to identify cannibalism and to measure the nutritional or other benefit gained by the attacker.

In some circumstances, patterns of genetic relatedness do seem to influence the evolution of cannibalism. Adult eggs of the flour beetle, *Tribolium confusum*, are often eaten by larvae and pupae by adults. Crosses between populations with different cannibalistic tendencies show that the behaviour has a genetic basis⁵. Experimental populations founded by members of the same large and variable base population attain very different population size under identical conditions — largely because of differences in the rate of pupal cannibalism⁶. In high-productivity populations, 85 per cent of pupae survive to become adults, while in populations with low productivity and equilibrium size the survival rate is only 5 per cent.

Wade⁷ has recently made use of this genetic variation in behaviour to show that the evolution of cannibalism is affected by degree of relatedness as predicted by kinship theory. Laboratory populations of *T. confusum* larvae were offered eggs from full sibs, from half sibs or from unrelated individuals. Larval females which ate eggs laid on the average one egg more per day on reaching adulthood than did non-cannibals. After eight generations, the egg cannibalism rate was lowest in the full-sib group, intermediate in the half-sib and highest in the populations in which the larvae had been offered eggs from unrelated beetles.

Kin selection may also be involved in controlling cannibalism in vertebrates. In

the lemming *Dicrostonyx groenlandicus*, males kill the offspring of unrelated males, but do not attack their own young⁸. Young males of the gerbil *Meriones unguiculatus* will normally kill and eat any pups. However, experimental exposure to a pregnant female inhibits this behaviour⁹. As gerbils are monogamous and territorial, any pups which a male meets after an encounter with a pregnant female in nature are likely to be his own and hence to share a high proportion of his genes. In mice, however, in which males will mate with any available female, destruction of young by adult males continues throughout life. Pregnant female mice exposed to a novel male reabsorb the fetuses which have resulted from a previous mating, this 'prenatal cannibalism' may have evolved in response to the high probability of the young being eaten at birth by the unrelated male¹⁰. Such kinship effects may influence the demography of vertebrate populations. In pike, attacks on unrelated individuals mean that fewer young are produced in ponds founded by mixing two full-sib families than when members of only one family are used¹¹.

Kin selection is particularly likely to reduce cannibalism in organisms whose local populations are relatively inbred, so that their members have a rather high proportion of genes in common. Wade's experiments on *Tribolium* show this clearly, as an avoidance of sibling cannibalism evolved only in inbred populations. In experiments in which there was random mating among the evolving stocks, no differences appeared among populations offered related or unrelated eggs. Computer simulations show that even a small amount of inbreeding greatly hastens the evolution of altruistic behaviour¹². It is often assumed that the social groups found in large mammals represent locally inbred populations and that their close kinship leads to the evolution of altruism and the avoidance of cannibalism among their members. However, detailed observation of individual mating patterns or the analysis of relatedness using genetic markers in lions and primates show that the members of a social group are not always particularly closely related to each other^{13,14} so that their behaviour cannot be explained simply by assuming that kin selection is operating.

A less ambiguous method of testing the importance of kinship effects has recently

become available with the realization that many hermaphrodite animals reproduce by self-fertilization¹⁵. This represents very close inbreeding. It might therefore provide an unusually direct way of examining the role of kinship in aggression and cannibalism, as in those species in which both selfing and outcrossing forms occur in the same population, outbreeders should be more likely to attack their relatively distant relations than are selfers

to destroy their close kin.

It is already clear that to cannibalize unrelated animals may increase the probability of survival of an aggressor's own genes. This may be an important factor in the evolution of behaviour, however much it conflicts with the widespread view that the struggle for existence is usually tempered by avoiding fatal interactions between members of the same species. □

Increasing atmospheric carbon dioxide and its consequences

from John G. Lockwood

NUMEROUS forecasts of the increase in atmospheric CO₂ that will result from the burning of fossil fuels have been made. The IIASA Energy Systems Programme¹ predicts an atmospheric CO₂ concentration of 430 to 500 p.p.m.v. in 2030 while The World Climate Programme² suggests values of 410 to 490 p.p.m.v. in 2025. Concentrations as low as 200 p.p.m.v. have been estimated for the end of the last glacialiation^{3,4}, even though levels may have been considerably higher in the more remote geological past. Recent observations show that the global mean CO₂ concentration in the atmosphere has increased from about 315 p.p.m.v. in 1958 to about 335 p.p.m.v. in 1979, a considerable increase over nineteenth century pre-industrial levels estimated at about 290 p.p.m.v.

Armed with forecasts of future fossil fuel needs and CO₂ production, how do we estimate the effect that these increasing concentrations will have? At a recent gathering in Norwich*, Gates (Oregon State University) argued that the problem is best approached using general circulation models (GCMs), which have the ability to portray many of the nonlinear feedback processes which serve to regulate atmospheric (and hence climatic) changes. The first application of a GCM to the CO₂ climate problem⁵ used an idealized geography with a swamp-like ocean and annually averaged insolation, and predicted that a doubling of atmospheric CO₂ would result in a 2–3K increase of globally averaged surface air temperature. This first attempt also showed the warming to be several times larger in high latitudes than at the Equator, and the globally averaged precipitation to be increased by a few per cent.

In subsequent simulations with GCMs

including more realistic geography and seasonal variations, generally similar results (global temperature increases of about 2K for a doubling of CO₂) have been found, such GCMs indicate that the largest warming will occur in the winter in high latitudes, with the summer precipitation shifted slightly polewards along with increased surface dryness in mid-latitudes. Flohn (University of Bonn) noted that high-latitude warming could lead to the disappearance of the perennial Arctic sea-ice and changes in the mass balance of the Antarctic ice sheet. In contrast, the zero-order, purely optical effect of doubling atmospheric CO₂, according to Kandel (CNRS), would be an increase of about 0.2K in surface temperature, but depending on what is assumed about various feedback mechanisms, such as atmospheric temperature, humidity, lapse rate, evaporation and clouds, this zero-order sensitivity may be multiplied by a factor ranging from 0.1 to 50.

Detection studies are now being directed by Wigley and Kelly (University of East Anglia) towards isolating those parts of observed climate fluctuations that are attributable to increasing atmospheric CO₂. This involves detecting what is at present a relatively weak signal in the presence of considerable noise. Climatic changes during the past century can partly be explained by increasing atmospheric CO₂ with contributions from volcanic activity. However, on the basis of the results so far it seems unlikely that a CO₂ signal will be detected with high confidence before 1990. Nevertheless, it looks as though CO₂-induced warming could become a major climatic factor by the middle of the next century. □

A growing role for reverse transcription

from Harold E Varmus

THE viruses resembling human hepatitis B virus that were recently discovered in other animals — woodchucks¹, ground squirrels² and domestic ducks³ — have begun to yield their anticipated harvest. In the June issue of *Cell*, J Summers and W Mason (Institute for Cancer Research, Philadelphia) make a strong case, based upon work with the duck virus, for the novel idea that RNA-directed DNA synthesis ('reverse transcription') is central to the life cycle of hepatitis B viruses⁴. The claim that RNA tumour viruses (retroviruses) are not the only animal viruses to use a reverse transcriptase may have implications that reach well beyond virology, since a growing constellation of eukaryotic genetic elements — various pseudogenes^{5,6} and repetitive sequences⁷ — appear to depend upon reverse transcriptases of unknown provenance for their existence or amplification. It is not necessary, however, to venture beyond the human hepatitis B virus itself to appreciate the significance of the new findings: this virus is currently replicating in about 200,000,000 people⁸ and infection is strongly associated with the most common

reactions *in vitro*. In infected duck livers, on the other hand, Mason, Summers and their colleagues recently observed that single-stranded putative intermediates in DNA synthesis were composed exclusively of 'minus' strands¹³. The asymmetrical properties of the two strands of hepatitis B viruses appear inconsistent with semi-conservative patterns of DNA replication, instead, the picture more closely mimics retroviral DNA synthesis, in which a virion-associated enzyme synthesizes a 'minus' DNA strand from an RNA template and a 'plus' strand from the 'minus' strand¹⁴.

Past efforts to understand the life cycle of hepatitis B viruses and make sense of such asymmetries have been frustrated in part by the failure of any member of this virus class to grow in cultured cells. Summers and Mason⁴ have circumvented this problem using materials from ducks naturally infected with the duck hepatitis B virus (DHBV). Their experiments required two crucial reagents isolated from cytoplasmic extracts of infected livers: viral cores that exhibit 'endogenous' DNA polymerizing activities, and deproteinized viral nucleic acids that work as templates in reactions 'reconstructed' with a retroviral reverse transcriptase. Synthesis of DHBV 'minus' strand DNA, in either the 'endogenous' or the 'reconstructed' reaction is resistant to the DNA intercalating agent, actinomycin D, whereas synthesis of the 'plus' strands in either reaction is sensitive to the drug. Furthermore, the growing 'minus' strands are partially associated with RNA and largely sensitive to a single-strand-specific nuclease, whereas the 'plus' strands are present entirely in DNA-DNA duplexes. These findings have been interpreted to mean that 'minus' strands are synthesized from templates of DHBV RNA and that 'plus' strands are synthesized from templates of 'minus' strand DNA.

The general picture that emerges from this work reveals the life cycles of hepatitis B and retroviruses to be temporally permuted versions of each other. Infectious particles of retroviruses contain viral RNA, viral DNA is synthesized in the cytoplasm early after infection and used in turn as a template for repeated synthesis of genomic RNA later in the infection. Infectious hepatitis B virus particles, in contrast, contain incompletely double-stranded DNA, the product of reverse transcription, viral RNA must be made during an early step in the life cycle and used as template for reverse transcription within cytoplasmic cores in the late phase.

The gross similarities in replication strategy, however, should not obscure a host of intriguing questions that address contrasting aspects of DNA synthesis, viral persistence and oncogenesis by these two

classes of viruses. Unlike retroviral reverse transcriptases, the hepatitis B DNA polymerases have not yet been solubilized to allow the enzymological study they deserve, so these proteins and their activities remain basically unknown. (The enzymes, incidentally, are probably virus-coded, since both the human¹⁵ and woodchuck¹⁶ hepatitis B genomes maintain a large unassigned open reading frame adequate for a protein of molecular weight about 90,000.) One clue to the enzymatic differences may reside in the mechanism of priming. Retroviruses use host tRNA to prime synthesis of the first strand of DNA, hepatitis B viruses, on the other hand, have an unidentified protein linked to the 5' end of 'minus' strand DNA¹⁷. Is it possible that the primer is a protein, as in the synthesis of adenovirus DNA^{18,7}?

Both retroviruses and hepatitis B viruses establish persistent infections, but again important differences are evident. Retroviruses perpetuate their genomes in infected cells by efficient and precise integration of DNA that resembles a transposable element and forms a suitable template for long-term synthesis of viral

Fig. 1 Genome structure of hepatitis B-like viruses. Δ , covalently bound protein

fatal cancer of man, primary hepatic carcinoma⁹.

Among the clues that led Summers and Mason to consider a replicative mechanism involving reverse transcription were the asymmetrical features of hepatitis B virus DNA, identified in both virus particles and infected cells. The viral DNA genome, as found in particles isolated from sera, is composed of one 3.2 kilobase strand of fixed chemical polarity (the 'minus' strand) base-paired with a shorter 'plus' strand of variable length¹⁰. (Because the 5' ends of these two strands invariably overlap by about 300 bases¹¹, the genome is in a circular configuration, although neither strand is itself a closed circle, see Fig. 1.) A DNA polymerizing activity in virus particles, first discovered in the human virus several years ago by Kaplan *et al.*¹², extends only the 'plus' strand during

Harold E Varmus is a Professor in the Department of Microbiology and Immunology, School of Medicine, University of California, San Francisco, California 94143

Fig. 2 The pathway for replication of the genome of hepatitis B-like viruses proposed by Summers and Mason⁴

RNA¹⁴ Little is known about the integration of hepatitis B DNA during productive infection of the liver, but the first detailed account of integrated viral DNA in woodchuck liver tumours, again by Summers and his colleagues¹⁹ in the same issue of *Cell*, reveals complex rearrangements within multimeric viral inserts. Similar rearrangements have been found in integrated DNA from a human hepatoma cell line (W. Rutter, personal communication). This picture is not conducive to a belief that integrated DNA

has a role in the life cycle. But if ordered integration does not occur, how is the genome maintained during persistent infection? In particular, what is the template for synthesis of valid copies of viral RNA?

A final comparison of retroviruses and their new cousins is at once the most obvious and the most mysterious: are the hepatitis B viruses truly oncogenic agents and do they use mechanisms recently discovered to influence the development of tumours by retroviruses? □

serotonin, noradrenaline, thyrotropin-releasing hormone and somatostatin — are preserved, indicating that death of nerve cells, rather than a change in afferent inputs, initiates the disease.

Attempts to produce animal models to mimic the pathology, the movement disorder, or the neurochemistry of the disease have received wide attention in recent years. Despite the large number of neurologic mutations that have been described in rodents, particularly mice, none has been identified which shows the key pattern of normal development, followed by cell death in a selected region of the central nervous system. Such mutants, if discovered, might provide a useful clue to the factors that lead to maintenance of cell integrity and an opportunity to study local trophic influences or lack thereof.

The local injection of neurotoxins, the most important of which is kainic acid^{2,3}, has provided a way of mimicking some of the effects of Huntington's disease. There is evidence that the principal neurotransmitter in the corticostriatal pathway, which forms a major input to the striatum, is glutamate, an excitatory neurotransmitter. Kainic acid, a rigid, cyclic analogue of glutamate, has potent excitatory effects, and when injected locally into brain tissues that contain glutamate receptors, causes neuronal death. Cells die, but incoming terminals survive, and many of the biochemical changes of Huntington's disease are seen. Because the effects of kainate require an intact corticostriatal system (the drug is less effective in animals that have previously had surgical corticectomy), it has been proposed that an endogenous kainate-like substance may overstimulate the corticostriatal system with cell death arising from an excitotoxic effect. Kainic acid receptors have been described in the brain and Coyle and his associates³ are currently searching for an endogenous substance with kainate receptor binding capacity. Additional evidence for the importance of afferent inputs to the striatum in determining the neurotoxic effects of kainic acid is provided in the paper by Berger *et al* in this issue of *Nature* (p 254). Depletion of serotonin by injection of 5,7-dihydroxytryptamine, a serotonergic neurotoxin, into the brain stem is shown to make striatal cells more resistant to kainic acid. The kainic acid model, although unlikely to provide a clue to the basic genetic defect in Huntington's disease, does hold some promise for assessing the effects of striatal lesions and perhaps for testing the effectiveness of various therapies.

An alternative approach has been to search for evidence of a generalized defect in cellular functions in Huntington's disease by investigation of peripheral non-neuronal cells more accessible to study. Initial indications of *in vitro* abnormalities in fibroblast growth rates and sus-

Huntington's disease: genetically programmed cell death in the human central nervous system

from Joseph B. Martin

HUNTINGTON'S DISEASE, characterized by involuntary movements and progressive dementia, is transmitted as an autosomal, dominant trait whose effect is not seen until the third or fourth decade of life. The tragedy of the disorder lies not only in the effects of the disease itself, but in the absence of any genetic marker to diagnose those at risk, hence transmission of the disease to offspring commonly occurs before symptoms develop. Any inquiry into the cause of the disease must tackle this central issue of how a gene mutation can permit normal development, integration and function of neuronal systems for some thirty to forty years and yet then bring about the relentless, regionally selective, premature death of neurones.

The caudate nucleus and putamen (striatum) are the most severely affected, but other regions of the basal ganglia, hypothalamus and brain stem are also involved. The loss of neurones in the striatum has not been seen to be accompanied by any cytopathology or tissue reaction and cells appear to die without inducing a local

response. Other cells and systems of the body appear unaffected. Dementia becomes severe, but its characteristics are strikingly different from those of the more common Alzheimer's disease, and at autopsy, although the cerebral cortex is diminished in overall size, no certain decrease in total numbers of cells has been unequivocally demonstrated.

How can one account for such a course of events and how can research strategies approach a solution to the problem? The discovery that the symptoms of Parkinson's disease are due to a dopaminergic deficiency secondary to degeneration of the pigmented nigrostriatal system provided strong grounds for investigating biochemical changes in Huntington's disease. Within the striatum and often in the neural projections from it, there is a decrease in the concentrations of the neurotransmitters, acetylcholine and GABA, and of the neuropeptides, substance P, enkephalin and cholecystokinin¹. These decreases in transmitter concentrations appear to be associated with the cell death since their concentrations remain normal in other regions of the brain. Tissue concentrations of other transmitters in the afferent pathways to the striatum — including dopamine,

Joseph B. Martin is Bullard Professor of Neurology in the Massachusetts General Hospital, Harvard Medical School, Boston 02114

ceptibility to irradiation have not been adequately confirmed⁵ Studies of differences in red cell membranes by electron spin resonance and of abnormalities in $(Na^+ + K^+)ATPase$ have not been replicated^{6,7} To date one cannot point to any described abnormality of other cells which provides an indication or marker of the genetic defects

Perhaps the answer will ultimately come from the new techniques of molecular genetics The Huntington's disease gene is considered to have a penetrance of 100 per cent and the mutation rate is exceedingly low, indeed, no proven cases of sporadic mutation have ever been described which satisfy the criteria of proven parentage, with parents surviving to an old age without symptoms, pathologically proven Huntington's disease in the new case, and subsequent transmission to a child The low mutation rate makes it possible and practicable to search for a DNA polymorphism which might be useful as a genetic linkage marker⁸ So far the

chromosomal localization of the defect is unknown but restriction endonuclease digests of DNA collected from the peripheral white blood cells of patients with the disease, combined with somatic cell hybridization, are being used to localize the polymorphisms to a specific chromosome In the long term, it should be possible to survey each chromosome in the human genome sequentially, first for a polymorphism to provide a genetic linkage and ultimately to localize the gene itself There will then be a real possibility of identifying the metabolic defect □

Rapid environmental and climatic changes

from D Q Bowen

THE successful characterization and evaluation of past rapid changes in the environment and climate depend largely on the integrity and sensitivity of dating methods All too often imprecision in the climatic record stems from dating uncertainties, with bioturbation and a variety of lag effects providing additional problems Given these constraints, it is little wonder that much of a recent meeting* on the character and timing of rapid environmental and climatic changes was devoted to the comparatively well-dated Holocene record and, to a lesser extent, to that of the later part of the last glaciation Small-scale systems of generally short duration, but for which detailed data were available, received far more attention than the larger systems with somewhat coarser data available over longer time scales

At the larger end of the scale it is difficult to identify specific climatic causes for changes in climate (R V Barry, University of Colorado, Boulder) Among the many uncertainties are whether fluctuations on the 100-1,000 year scale are due to longitudinal and/or latitudinal changes in circulation, whether particular regimes persist for long periods and what the circulation

variability of different regimes is It is not even possible to ascribe the quasi-persistent types of circulation regime to external or internal forcings, to atmospheric auto-variation or to internal feedback mechanisms between land, ocean and atmosphere Barry stressed, however, that the intensity and timing of climatic change will show considerable geographical variation step-like in some areas but more gradual in others

R Bryson (University of Wisconsin, Madison) further stressed that in regarding climatic change as essentially nonlinear, a major break with tradition had now occurred, while J Mitchell (Environmental Data Service, Silver Spring, Maryland) emphasized the role of the oceans as a global climatic fly-wheel which limits change more strictly over shorter than over longer periods Deep water formation in the North Atlantic may also play an important part in speeding glacial events, sea-level changes can lead to perturbations in oceanic thermocline circulation processes which may enhance oceanic heat transportation to higher latitudes during periods of glacial growth (C Rooth, University of Miami)

Global data show considerable glacial fluctuations during the last glaciation, mostly reflecting local or anomalous conditions (S Porter, University of Washington, Seattle) and the glacier response to rapid climatic change is best assessed from Holocene examples where

lead and lag effects can be partially quantified Sea-level data for the past 140 kyr (T Cronin, US Geological Survey, Reston) demonstrate the many pressing problems still extant, where was the last glacial maximum sea level? Where was sea level during the mid-Wisconsin? How rapid were sea-level changes? The possibility of a high sea-level event between 130 and 140 kyr received much attention but was strongly questioned by W Ruddiman (National Science Foundation) on the basis of the oxygen-18 record

The most sensitive indications of climatic change are provided by the oxygen-18 record in ice sheets followed by sea-surface temperatures (H Wright, University of Minnesota, Minneapolis) Most pollen records are beset by persistent difficulties in interpretation due to their proximity to ice sheets Sensitivity and response times might thus be better detected at very low latitudes or in the Southern Hemisphere, free from such influences Furthermore the climatic signal from pollen data fails to provide a clear record of climatic change of short duration even when its amplitude is large (M Davis, University of Minnesota) for example, the 'Little Ice Age' is only recorded clearly by pollen at a few sites, despite the considerable impact on human culture Except in a few cases it is difficult to infer from pollen data whether climatic change is step-wise or gradual and unidirectional (W Watts, Trinity College Dublin) Relationships between climatic change and the pollen record are only indirect because plant populations generally become established long after causal climatic events There is thus an urgent need to identify sensitive ecotonal areas at the margins of plant ranges where pollen data and climate can be linked directly Most rapid of all may be the response of lake sediments to climatic change (R Anderson, University of New Mexico, Albuquerque) Seasonal control is dominant and gives a clear signature, while cumulative changes in seasonal components demonstrate rapid climatic change It should be possible to design transfer functions expressing linkages between climate and sedimentation, with eventual application to non-varied sediments

In summing up the proceedings, J Mitchell predicted that climate will change over a transitional period of the next 200 years because of an increased carbon dioxide content in the atmosphere, then settle into a 1,000 year equilibrium state The rapidity of this transition could be comparable to that at the Younger Dryas to Holocene change some 10,000 years ago. □

Erratum

A Proterozoic Pangaea?

from D.H. Tarling

IN a recent review of palaeomagnetic data (*Earth planet. Sci. Lett.* **59**, 61; 1982), Piper concludes that a single huge continent, Pangaea, existed throughout the Proterozoic period of the Earth's history (2,600–570 Myr ago). Such a conclusion is consistent with many geological features that indicate extensive continental stability during this period, yet Piper's analyses also require that this Pangaeian supercontinent was in motion relative to the Earth's axis of rotation. Such motion must, presumably, be associated with the same mantle convective motion that currently results in continental splitting and ocean-floor spreading. Piper's conclusions are thus of fundamental importance in testing some of the basic assumptions in both palaeomagnetism and plate tectonics.

Palaeomagnetic studies allow the determination of the palaeolatitude and orientation (relative to the palaeomagnetic pole) of the sampled area. Where sufficient data are available, they can be used to construct a palaeomagnetic polar wandering curve, indicating the changing position of the pole relative to the stable tectonic block from which the samples were obtained. Such curves do not, in fact, mean that the pole is moving, as this is fixed relative to the ecliptic, but results from a movement of the sampled region relative to the pole. The fact that polar wandering curves exist for the Proterozoic is thus of the utmost importance as it clearly indicates that the continent, or continents, were in motion and were presumably driven by mantle convection.

If polar wandering paths for the same period of time can be matched between different tectonic units, then the relative positions of these tectonic units can be precisely defined. Thus the palaeomagnetic data from the different cratonic blocks of the world can be used to determine the existence, or not, of one or more continental units during the Proterozoic. Piper finds that he can define Pangaea throughout the Proterozoic as a cigar-shaped continent comprising Australia, China, India and Antarctica backing onto western South America–Africa, with Kazakhstan–Siberia against North Africa and bordering onto western Laurentia (North America, Greenland and Europe). Piper finds that such a continent is not only required by the palaeomagnetic data but is also consistent with the available geological evidence.

It is only too easy to be sceptical about the data base on which any such model is

erected. Even with a single craton, the radiometric dating of any intrusive event is uncertain within 100–200 Myr, even ignoring problems of open chemical systems, during which time major continental motions could have occurred. It is also worrying that much Precambrian data are based on alternating magnetic field demagnetizations — a technique that is 'noisier' than thermal demagnetization — yet thermal demagnetization is often apparently ineffective in determining discrete components of remanence. Even when such components can be isolated, there is doubt about their age. There is a tendency to assume that the component with the highest stability is, in fact, the oldest — yet this may simply reflect the presence of haematite that may have formed very much later than the rock itself. Even when such components have been isolated and dated, it is rare for there to be adequate tectonic control of subsequent movements, although the Proterozoic crust appears to have been little deformed as the overlying sediments tend to have only shallow dips. The uncertainties involved are thus immense and require subjective evaluation. Unfortunately, this

can lead to the syndrome in which scattered data are examined and the odd points that are near to previous observations are accepted for publication and the remainder appear, if at all, in the inaccessible appendix of a thesis. Despite Piper's attempts to be objective, therefore, the data may well already have been subjectively selected to conform to previous data or models. However, the only way in which such problems can be resolved is by the erection of specific models which can then be tested by a variety of methods and by new data.

This is not Piper's first model and it seems unlikely to be his last. However, the fact that he can make a very plausible case for support of his model is, in itself, of great importance. It demonstrates, for example, that continental motions occurred, thus indicating the action of mantle convection currents. This is no great surprise in view of the much higher radiogenic heat production in the past, but raises the problem of why such motions did not cause continental splitting, as they do now and also did in pre-Proterozoic times. The implication is that the continental lithosphere, in Proterozoic times, was too strong or too thick to be split by such motions. But how did such a thickness develop suddenly at the end of Archaean times and what caused the change to present-day continental splitting? □

The sunflower seed protection business

from Peter D. Moore

The consumption of the seeds of plants by invertebrate and vertebrate predators is a serious problem for the agronomist, and much effort has been devoted to finding ways of limiting the predators' numbers. There is, however, a quite different way of tackling the problem. In a recent paper¹, field trials are reported of attempts to protect economically important seeds by buying off the predators with an abundant supply of another seed.

In many North American forests, small mammals have often been found responsible for seed predation and depression of woodland regeneration, in particular the douglas fir (*Pseudotsuga menziesii*) has been much studied. That seed predators may limit the regeneration of plant species has been known for some time. As long ago as 1919 Watt's² records of the fate of acorns in oakwoods showed that high mortality of acorns in oakwoods could be largely put down to predation by birds and mammals. He also found that in the case of beech², invertebrates were involved and concluded that the low level of regeneration found in British woodland was a consequence of

seed predation. The high population density of mice and voles, regarded by him as major culprits, could in turn be related to rearing of game birds and consequent destruction of predators, a view supported and popularized by Tansley³.

The possibility that the problem might be overcome through providing an alternative food source was first approached experimentally by Sullivan⁴ who supplied deer mice (*Peromyscus maniculatus*, a major seed predator of douglas fir) with sunflower seed in order to distract it from the conifer seed. He found that very large quantities of sunflower seed had to be provided (seven sunflower seeds for every douglas fir seed) in order to reduce predation significantly.

Sullivan and Sullivan⁵ have now repeated these experiments with lodgepole pine (*Pine contorta*) in an area of British Columbia from which the pine had been

D.H. Tarling is Reader in Palaeomagnetism in the Department of Geophysics, The University, Newcastle upon Tyne NE1 7RU.

Peter D. Moore is Senior Lecturer in the Department of Plant Sciences at King's College, University of London.

felled in 1978. Lodgepole pine was seeded at a density of 45,000 ha⁻¹ and, in some experimental plots, sunflower seed was added at twice this density (90,000 ha⁻¹). Damage by mice was very high in plots without the sunflower additive (often less than 5 per cent survival after 5 months), but where sunflower seed was also sown, pine seed survival was around 25 per cent after 5 months. This fivefold increase in the rate of survival is obviously of great interest to the forester.

There are two complications, however, which lead to a certain degree of apprehension. The first, which has received emphasis from Harper⁶, is that compensating factors may be operating so that when one cause of mortality is reduced another assumes prominence. The second is the fear that a rich new resource of sunflower seeds may cause an increase in mouse population density, which will subsequently lead to greater predation upon the pine seeds. Sullivan and Sullivan claim that such increases in mouse density were observed in the sunflower plots only where initial densities were below 5 mice ha⁻¹, so other population limits are evidently in operation. It also appears from their data that no other cause of pine seed mortality has replaced that due to predation, so the technique seems to warrant more extensive trials.

Ecological, or perhaps ethical, attitudes have evidently changed since the days of Watt and Tansley. Instead of shooting the predators we now feed the mice. □

Glomar Challenger at the Cretaceous-Tertiary boundary

from Audrey Wright, Ross Heath and Lloyd Burckle

THE drilling vessel *Glomar Challenger* reached Yokohama on 20 June 1982, after sampling six sites in the western North Pacific. Major objectives of this leg were to determine the chronology and extent of late Neogene through Pleistocene migrations of the subarctic front; to acquire a Cenozoic record of aeolian and authigenic sedimentation in the North Pacific; and to collect an undisturbed sample of the Cretaceous-Tertiary boundary on Shatsky Rise.

Hydraulic piston cores taken at four sites located along a north-south transect from 34° to 44°N latitude and centred at about 155°E longitude recovered a suite of siliceous sediments for in-depth palaeoceanographic and palaeoclimatic reconstructions for the past five million years. Sediments from two 'red clay' sites, located east and west of Shatsky Rise, provide an excellent basis for resolving Cenozoic North Pacific authigenic sedimentation as well as for detailing the depositional history of wind-blown sediment from Asia.

At Site 577 on the Shatsky Rise, a complete and expanded sequence containing the Cretaceous-Tertiary (K-T) boundary was collected. Triplicate hydraulic piston cores were successfully taken through this critical interval, guaranteeing complete coverage and sufficient material for detailed study of floral and faunal changes as well as palaeomagnetic and geochemical properties across the K-T boundary. Studies of the foraminifers, nannofossils, palaeomagnetic signature and aeolian debris from this section, begun at sea, will be continued

on-shore in the laboratories of cruise participants.

Initial examinations of the calcareous nannofossils and planktonic foraminifers suggest that the K-T boundary, located at a sub-bottom depth of 109.7 m, is continuous and complete. The abundance of the late Maestrichtian *Micula mura* nannofossil assemblage decreases abruptly at the boundary. Above it, Cretaceous species are replaced by a less diverse, less abundant and moderately preserved assemblage characterized by the genera *Thoracosphaera* and *Cyclagelosphaera*, as well as *Markalius astroporus* and the very small *Cruciplacolithus primus*. Few reworked Cretaceous forms were found 20 cm above the boundary.

Preservation of foraminifers is moderate to good throughout the boundary interval. The K-T boundary is marked by the extinction of all Cretaceous planktonic forms and the first appearance of the early Palaeocene foraminifer *Chiloguembelina taurica*. Rare reworked Cretaceous foraminifers are found at least 20 cm above the boundary. The first appearance of the primitive globigerinid foraminifer, *Globigerina eugubina*, occurs 40 cm below the boundary. At this point the specimens are few in number and very tiny. They become abundant and of a consistently larger size at the boundary. These preliminary findings are in contrast with the section at Gubbio, Italy, in which the first appearance of *G. eugubina* marks the K-T boundary. □

A SOLAR PRINTING PRESS

It was mentioned in a recent number of this journal that a printing press worked by solar heat had been exhibited in the Tuileries Garden in Paris on the occasion of a *fête*. The solar generator was devised by M. Abel Pifre. The insolator, shown in the middle of the picture, measured 3'50 m. diameter at the aperture of the parabolic mirror. It was set up in the garden, near the large basin, at the foot of the flight of steps of the Jeu de Paume. The steam from the boiler placed in its focus was utilised by means of a small vertical motor (shown on the left), having a power of 30 kilogrammetres, which actuated a Marinoni press (on the right). Though the sun was not very ardent, and the radiation was hindered by frequent clouds, the press was worked with regularity from 1 p.m. till 5.30 p.m., printing on an average 500 copies an hour, of a journal specially composed for the occasion, viz., the *Soleil Journal*. This result, though not indicating a revolution in the art of printing, may enable one to judge of the services these *insolators* may render in climates with a radiation more powerful and constant. Sharp edges of planetary rings

Nicole Borderies & Peter Goldreich

Division of Geological and Planetary Sciences, California Institute of Technology, Pasadena, California 91125, USA

Scott Tremaine

Department of Physics, Center for Space Research and Center for Theoretical Physics, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139, USA

The ring systems of Saturn and Uranus exhibit several sharp edges across which the optical depth drops from order unity to essentially zero. At least two and perhaps all of these features are associated with the location of orbital resonances between a satellite and the ring particles. It is remarkable that the optical depth varies on a distance scale which is much finer than that over which angular momentum can be transferred between a satellite and the ring material. The important features of this phenomenon are (1) A perturbed band of width $\Delta a/a \approx (M_s/M_p)^{1/2}$ adjacent to the edge within which the angular momentum transfer occurs (2) Streamlines perturbed such that the angular momentum luminosity decreases smoothly across the band to zero at the edge even though the optical depth remains constant (3) Dynamical equilibrium requires a relation between the random velocity, the rate of deformation and the optical depth

SHARP edges are common features of planetary rings¹. Stellar occultation observations of the rings of Uranus revealed edges which are sharp at a resolution of a few kilometres². Stellar and radio occultations carried out by the Voyager spacecraft revealed several sharply defined gaps and ringlets in the saturnian ring system (refs 3, 4 and L. Tyler, personal communication). Of these, perhaps the most interesting are the outer boundaries of the classical A and B rings which are sharp on a scale of hundreds of metres. Voyager discovered that the outer boundary of the A ring is virtually coincident with the 7:6 resonance of the larger co-orbital satellite⁴ and confirmed the prediction that the outer boundary of the B ring is located at the 2:1 resonance with Mimas^{5,6}. On the basis of these two examples, we adopt the hypothesis that a satellite resonance is associated with every sharp edge across which the optical depth falls to zero.

Here we consider the dynamics in several stages. First, we review some relevant material about periodic orbits and particle disks, and then we prove that the ring particle velocity dispersion is greatly enhanced near a sharp edge. Next, we show how the angular momentum luminosity gradually decays to zero even though the surface density and velocity dispersion do not vary appreciably. Finally, we indicate why the surface density remains high until it drops abruptly to zero over a distance from the edge comparable to the vertical thickness of the ring.

The semi-quantitative arguments presented here are, in part, based on numerical calculations of ring equilibria near an edge, the results of which we shall publish elsewhere. For ease of notation, and because the outer A and B ring boundaries are among the best studied examples of sharp edges, we have concerned ourselves only with outer edges; the discussion can be translated easily to render it applicable to inner edges.

Periodic orbits

The perturbation potential near an isolated resonance is characterized by an azimuthal wavenumber m and a pattern speed Ω_p . In a reference frame which rotates with the pattern speed, the potential varies as $\cos m\varphi$ with longitude φ .

There is a set of test particle orbits, referred to as periodic orbits, which are closed in the rotating frame. In the inertial frame the periodic orbits are precessing ellipses. For small

eccentricity, the shapes of the orbits in the rotating frame satisfy

$$r = a \left[1 + \Gamma \frac{M_s a}{M_p (a - a_r)} \cos m\varphi \right] \quad (1)$$

where r is the radial distance from the centre of the planet, a is the semi-major axis, M_s and M_p are the masses of the satellite and planet, respectively, and Γ is of order unity. The eccentricity increases with decreasing distance from the resonance which is at semi-major axes a_r . In a region of width

$$\Delta a \approx a_r (M_s/M_p)^{1/2} \quad (2)$$

around a_r , the periodic orbits intersect

Streamlines

The ring particle streamlines are described by

$$r = a \{ 1 - e(a) \cos m[\varphi + \Delta(a)] \} \quad (3)$$

in the rotating frame. Here a and e are the semi-major axis and eccentricity of the ring particle orbits and Δ is a phase lag. The determination of e and Δ from the viscous stress and gravitational perturbations due to the satellite and the ring material is described later. The outer edge a_0 is near a_r , and for $(a_0 - a)/\Delta a \gg 1$, the streamlines are well approximated by periodic orbits. Closer to a_0 , the self-gravity of the ring material and the interparticle stress modify the streamlines so that they do not cross.

For later use, we define

$$J(a, \varphi) = \frac{\partial r}{\partial a} \bigg|_{\varphi} = 1 - q \cos [m(\varphi + \Delta) + \gamma] \quad (4)$$

where

$$q^2 = \left(\frac{a de}{da} \right)^2 + \left(\frac{mae d\Delta}{da} \right)^2, \quad \text{sgn } q = \text{sgn} \left(\frac{de}{da} \right) \quad (5)$$

and

$$\tan \gamma = \frac{me d\Delta/da}{de/da}, \quad -\frac{\pi}{2} \leq \gamma \leq \frac{\pi}{2} \quad (6)$$

Viscosity

A rigorous treatment of the viscous stress in a particle disk of modest optical depth requires the derivation of the full stress tensor from kinetic theory. The Boltzmann equation with col-

isions has been solved for perturbed particle disks⁷ We rely on this calculation for guidance but for simplicity we use the hydrodynamical approximation and relate the viscous stress to the deformation rate tensor by a single parameter, the kinematic viscosity, ν

For an unperturbed keplerian disk it is a good approximation to take

$$\nu \approx 0.5 \frac{v^2 \tau}{\Omega(1+\tau^2)} \quad (7)$$

where v is the one-dimensional r.m.s. random velocity⁸ For simplicity, we ignore the real complications introduced by anisotropic random velocities and the distribution of particle sizes It is qualitatively acceptable but quantitatively inaccurate to extend the use of equation (7) to regions perturbed by resonances

The rate of dissipation of mechanical energy per unit mass is expressed macroscopically by

$$\frac{dE_v}{dt} \approx 2\nu |S|^2 \quad (8)$$

and microscopically by

$$\frac{dE_v}{dt} \approx (1-\varepsilon^2) \nu^2 \Omega \tau \quad (9)$$

Here S is the rate of deformation tensor and ε is the coefficient of restitution for particle collisions Equating the two expressions for viscous dissipation and using equation (7) for ν , we obtain

$$\varepsilon^2 \approx 1 - \frac{G(q^2)}{1+\tau^2} \quad (10)$$

where

$$G(q^2) \approx |S/\Omega|^2 \quad (11)$$

If $\varepsilon(\nu)$ were known, equation (10) would determine ν as a function of q^2 and τ Unfortunately, we can be confident only that $d\varepsilon/d\nu < 0$, $dG/d|q| > 0$ and $G \rightarrow \infty$ as $|q| \rightarrow 1$ However, we can draw one important conclusion from equation (10) that is, in steady state the magnitude of the rate of deformation is bounded such that

$$|S| \lesssim \Omega(1+\tau^2)^{1/2} \quad (12)$$

An external stress might temporarily drive $|S|$ above the upper limit However, the random velocity would then grow exponentially, with rate constant $\Omega\tau$, until the viscous stress was large enough to reduce $|S|$ to an acceptable steady-state level

Angular momentum and energy fluxes

The angular momentum and energy fluxes, $F_H(a, \varphi)$ and $F_E(a, \varphi)$, are the rates at which these quantities cross a unit length of the streamline with semi-major axis a and longitude φ The luminosities $L_H(a)$ and $L_E(a)$ are the integrals of the fluxes around the streamline

The ring divides naturally into two regions, an inner unperturbed portion with $a < a_1$ and an outer perturbed part with $a_1 \leq a \leq a_0$ The location of a_1 need not be specified beyond the requirement that $\Delta a \ll a_0 - a_1 \ll a$

Unperturbed inner region. In the inner, or keplerian, region the streamlines are circles, $\Omega^2 a^3 = GM_p$, and

$$L_H(a) = 2\pi a F_H(a) = 3\pi \Sigma \nu \Omega a^2 \quad (13)$$

$$L_E(a) = \Omega L_H(a) \quad (14)$$

with Σ the surface density⁹ The radial drift velocity of a ringlet is

$$\frac{da}{dt} = -\frac{1}{\pi a^2 \Omega \Sigma} \frac{dL_H}{da} \quad (15)$$

and vanishes if L_H is conserved The viscous dissipation of energy per unit mass is

$$\frac{dE_v}{dt} = -\frac{1}{2\pi a \Sigma} \left[\frac{dL_E}{da} - \frac{\Omega dL_H}{da} \right] = \frac{3\Omega L_H}{4\pi a^2 \Sigma} = \frac{9\nu \Omega^2}{4} \quad (16)$$

Note that L_E decreases outwards even where L_H is conserved **Perturbed outer region.** Here the streamlines are not circular and the fluxes are functions of φ as well as of a The hydrodynamical approximation yields

$$F_H(a, \varphi) = 2\nu(a) \Sigma(a) \Omega a (1-q^2)^{1/2} \left[\frac{1}{J} - \frac{1}{4J^2} \right] \quad (17)$$

where $\Sigma(a)$ is the mean surface density averaged over φ and $\Omega(a)$ is the mean orbital angular velocity As $e(a) \ll 1$, $F_E = \Omega F_H$ If ν is assumed to be a function of a but not of φ , then

$$L_H(a) = 4\pi \nu \Sigma \Omega a^2 K(q^2) \quad (18)$$

where

$$K(q^2) = \frac{3-4q^2}{4(1-q^2)} \quad (19)$$

Of course, $L_E = \Omega L_H$

Two values of $|q|$ are of particular significance For $|q| = q_1 = 3/4$, $F_H = 0$ where $\cos[m(\varphi + \Delta) + \gamma] = \text{sgn } q$ For $|q| < q_1$, $F_H > 0$ for all φ and for $|q| > q_1$, there is an interval of φ in which $F_H < 0$ The inward flux of angular momentum arises because the angular velocity increases outwards in this longitude range For $|q| = q_2 = \sqrt{3}/2$, $L_H = 0$ For $|q| < q_2$, $L_H > 0$ and for $|q| > q_2$, $L_H < 0$

The existence of two transitional values of $|q|$ is established by our solution of the Boltzmann equation⁷ The particular numerical values, $q_1 = 3/4$ and $q_2 = \sqrt{3}/2$, are special consequences of the hydrodynamical approximation The more appropriate kinetic theory yields values which are functions of optical depth

Conditions near edges

Enhanced velocity dispersion. An outer edge may remain fixed at a resonance if the angular momentum which flows out from the unperturbed inner region, $L_H(a_1)$, is completely absorbed by the satellite Then, it follows from the Jacobi relation that energy is transferred to the satellite at a rate $\Omega_p L_H(a_1)$ The rate of energy dissipation in the perturbed region must be $L_E(a_1) - \Omega_p L_H(a_1) = (\Omega - \Omega_p) L_H(a_1)$ Most of this dissipation takes place in the narrow outer band of width Δa in which the streamlines are severely distorted The average dissipation rate per unit mass in this band is

$$\frac{dE_v}{dt} = \frac{(\Omega - \Omega_p)}{2\pi a \Delta a \Sigma} L_H(a_1) \quad (20)$$

Comparison of equations (16) and (20) shows that dE_v/dt is enhanced in the outer band by a factor $2a(\Omega - \Omega_p)/(3\Omega \Delta a)$ relative to its unperturbed value Use of the resonance condition $m(\Omega - \Omega_p) = \Omega$ and $\Delta a/a \approx (M_s/M_p)^{1/2}$ allows us to simplify the enhancement factor to $m^{-1}(M_p/M_s)^{1/2}$

It is apparent from equation (8) that either or both ν and $|S|$ must increase in the outer band However, the upper limit on $|S|$ given by equation (12) proves that for $\tau = 0(1)$, most of the enhanced dissipation is due to an increased ν Since ν is proportional to v^2 , it follows that ν is enhanced by a factor

$$F \approx \left[\frac{1}{m^2} \frac{M_p}{M_s} \right]^{1/4} \quad (21)$$

Decay of L_H . It might seem peculiar that L_H would decay in the outer band where Σ is constant and ν is enhanced above its unperturbed value However, there is no paradox here

$L_H = 0$ for any values of Σ and ν if $|q| = q_2$. Thus $q_2 - |q| \ll 1$ in the outer band and $|q| = q_2$ at the edge

Sharp edges. We have seen how L_H can decay to zero in the outer band at constant Σ . However, one question remains why does Σ maintain a constant value right up to the edge?

To answer this, we refer to equation (10) which relates ε , τ and $|q|$. Since ε is a function (admittedly unknown) of ν , and τ is directly proportional to Σ , equation (10) may be viewed as connecting ν , Σ and $|q|$. But in the outer band, $|q| \approx q_2$ and ν is enhanced by a factor F above its unperturbed value. Thus, in principle, equation (10) determines Σ in the outer band as a function of the resonance parameter $m^{-1}(M_p/M_s)^{1/2}$ and the unperturbed ν .

The precise distance over which Σ drops to zero is probably of the order ν/Ω which is the vertical thickness of the ring and, for $\tau = 0(1)$, is also the mean free path for particle collisions. Our use of the hydrodynamical model is not valid closer than ν/Ω to the ring edge.

Numerical results

The dynamical state of the ring may be modelled by dividing it into narrow ringlets whose shapes are determined by the three variables a , e and Δ . The perturbation accelerations are due to the satellite gravity, the self-gravity of the ring and the viscous stress. We have derived the differential equations which govern the variations of a , e and Δ for each ringlet. The evolution equations are supplemented by equations (7) and (10) and one of several plausible relations for $\nu(\varepsilon)$.

Equilibrium solutions have been obtained with up to 20 ringlets. They exhibit the features discussed above. In particular, there is an outer band of width approximately Δa in which ν is greatly enhanced, $|q| = q_2$, Σ is fairly constant and L_H decays to zero. With some forms of $\varepsilon(\nu)$ we were unable to obtain equilibrium solutions for which Σ varies smoothly with a in the outer band. Presumably, the smooth equilibria suffer from a secular instability of the kind proposed to explain the multiple ringlet structure of Saturn's rings¹⁰⁻¹².

Single ringlet model for the outer band. Several characteristics of the numerical solutions may be illustrated by a crude model in which the entire outer band is represented by a single ringlet.

We balance the satellite torque on the ringlet

$$T_s = -(ma\Omega)^2 e \frac{M_s}{M_p} \Sigma a \Delta a |\sin m\Delta| \quad (22)$$

against the angular momentum luminosity which enters it, $L_H(a_1)$, to obtain

$$|\sin m\Delta| = \frac{\nu}{\Omega(ma)^2} \left(\frac{M_p}{M_s} \right)^2 \quad (23)$$

where ν is the unperturbed viscosity. In deriving equation (23) we have set $e = \Delta a/a \approx (M_s/M_p)^{1/2}$. The condition that the satellite is capable of opening a gap at the resonance is equivalent to $|\sin m\Delta| \leq 1$ (ref. 13).

The values a_0 and e_0 for the outer edge depend on the parameters m , M_s/M_p and $\Sigma a^2/M_p$. At a strong resonance,

$|\sin m\Delta| \ll 1$ so that $q \approx a \, de/da$. Now $q \approx |q_2|$ in the outer band and, for our hydrodynamical mode, $q_2 = \sqrt{3}/2$. The expression

$$e \approx \left(\frac{M_s}{M_p} \right)^{1/2} \left[1 + \frac{\sqrt{3}}{2} \right] + \frac{\sqrt{3}}{2} \left[\frac{a - a_r}{a_r} \right] \quad (24)$$

takes into account the fact that the streamlines are well approximated by periodic orbits for $a < a_r - \Delta a$ and that $a \, de/da \approx \sqrt{3}/2$ for $a \geq a_r - \Delta a$. The condition that the outer edge streamline does not precess in the rotating frame is

$$\frac{\Sigma a^2}{M_p e_0} - \frac{m M_s}{e_0 M_p} \approx \frac{3(m-1)}{2} \left[\frac{a_0 - a_r}{a_r} \right] \quad (25)$$

The first and second terms on the left-hand side are due to the gravitational perturbations from the ring and the satellite, which force the apsidal line to advance and regress, respectively. For $p \equiv \Sigma a^2/(m M_s) \geq 0(1)$, equations (24) and (25) may be solved for $(a_0 - a_r)/a$ and e_0 . Both e_0 and $(a_0 - a_r)/a$ are proportional to $(p M_s/M_p)^{1/2}$ for $p \gg 1$.

Discussion

The Voyager 2 images show that the outer boundary of the B ring is an ellipse centred on Saturn whose short axis points approximately towards Mimas⁵. A calculation of the periodic orbits near the 2:1 resonance with Mimas indicates that the first orbits which cross have $ae = 30$ km. The observations yield $ae \geq 70$ km for the B-ring outer edge. This information may allow a local determination of Σ from more precise versions of equations (24) and (25).

The velocity dispersion and the vertical thickness should be enhanced by between one and two orders of magnitude in the outer band of the B ring relative to their unperturbed values. It is reasonable to assume that the enhanced collision velocities associated with resonance features such as sharp edges and density wavetrains would result in the copious production of small particles. These particles might account for the peaks in optical depth found near resonances in the UV spectrometry occultation data⁴. These peaks should then be absent from the radio occultation data.

The arguments presented in this article are based on the implicit assumption that outside a sharp edge $L_H = 0$, or at least is reduced far below its value in the unperturbed part of the ring. The possibility remains that although τ drops by one or even two orders of magnitude, ν might rise by a similar factor, thus maintaining L_H at its unperturbed value in a region which is apparently empty. The juxtaposition of high and low optical depth regions separated by a sharp boundary would then be an extreme limit of the secular instability proposed to account for the fine structure in Saturn's rings¹⁰⁻¹².

We thank E. Danielson, A. Lane, J. Lissauer, R. Terrile and L. Tyler for helpful discussions. Stratigraphical significance of the Tulu Bor Tuff of the Koobi Fora Formation

F. H. Brown & T. E. Cerling

Department of Geology, University of Utah, Salt Lake City, Utah 84112, USA

The Tulu Bor Tuff, a major marker horizon in the Koobi Fora Formation, has been misidentified in previous studies. Identification of this tuff in sediments previously mapped as the Kubi Algi Formation requires re-evaluation of the existing stratigraphical framework of the Koobi Fora region

DURING the past 2 yr we have investigated the chemistry of tuffs from Plio-Pleistocene deposits east of Lake Turkana in northern Kenya. The stratigraphy at Koobi Fora is based on marker beds and their supposed correlatives¹. We state specific locations where particular stratigraphical marker beds may be observed. This is necessary because miscorrelations have been made in erecting the type sections of formally defined formations, and because several stratigraphical terms now in use are defined only vaguely. In addition, we find that considerable stratigraphical revision is needed at Koobi Fora.

Stratigraphical problems at Koobi Fora have been evident for some time. By 1977 it had been shown² that chemical differences between the Tulu Bor Tuff in area 129 and what had been called the Tulu Bor Tuff in areas 15, 102 and 116 were significant. Identification of two distinct tuffs which had been previously mapped as the KBS Tuff also indicated that some miscorrelations had been made^{2,3}. Also in 1977 White and Harris⁴ stated that "suids from the lower Member of the Koobi Fora Formation (below the Tulu Bor Tuff) equate well with those from Member B. The Koobi Fora Formation lacks fossiliferous horizons equivalent in age to Shungura Members C through F, although there are indications that the Kubi Algi fauna may, in part, fill this hiatus", implying the Kubi Algi Formation must be partly equivalent to the Koobi Fora Formation^{5,6}. In 1981 Williamson⁷ defined 10 molluscan range zones in the type sections of the Kubi Algi, Koobi Fora and Guomde Formation must be partly equivalent to the Koobi Fora Formation^{5,6}. In 1981 Williamson⁷ defined 10 molluscan range zones horizons had been called the Tulu Bor Tuff and advocated substantial stratigraphical revision of the Kubi Algi and Koobi Fora Formations. Despite these disturbing observations, the same stratigraphical sections were published⁸ in 1981 as were published in 1973, with no comments about possible problems.

Stratigraphy and stratigraphical nomenclature

The stratigraphy of the Koobi Fora region has been widely discussed^{1,2,4,7-18}. In a reconnaissance study from 1970 to 1973 Bowen^{1,12} recognized three Plio-Pleistocene lithological units, the Kubi Algi Formation, the Koobi Fora Formation and the Guomde Formation. Only the Koobi Fora Formation was studied in detail, and was divided into the Upper, Lower and Ileret Members. Three stratigraphical levels were mapped during this study: the Suregei Tuff, the transition between the laminated siltstone facies and the facies above it (near the level of the KBS Tuff), and the Chari Tuff where it is overlain by the Guomde Formation¹²⁻¹⁴. Detailed mapping of the region followed (1972-80), and many additional marker horizons were recognized by Findlater¹⁵⁻¹⁸ and mapped throughout the region. In many cases the horizons mapped by Bowen were mapped differently by Findlater, but no reasons were stated for the changes.

In 1977 White and Harris⁴ published a tuff indexing system, and recorded the type areas of the named marker beds. Vondra and Bowen¹⁴ eliminated the Ileret Member in 1978, and redefined the lower boundary of the Upper Member of the

Koobi Fora Formation as the first channel conglomerate above the KBS Tuff.

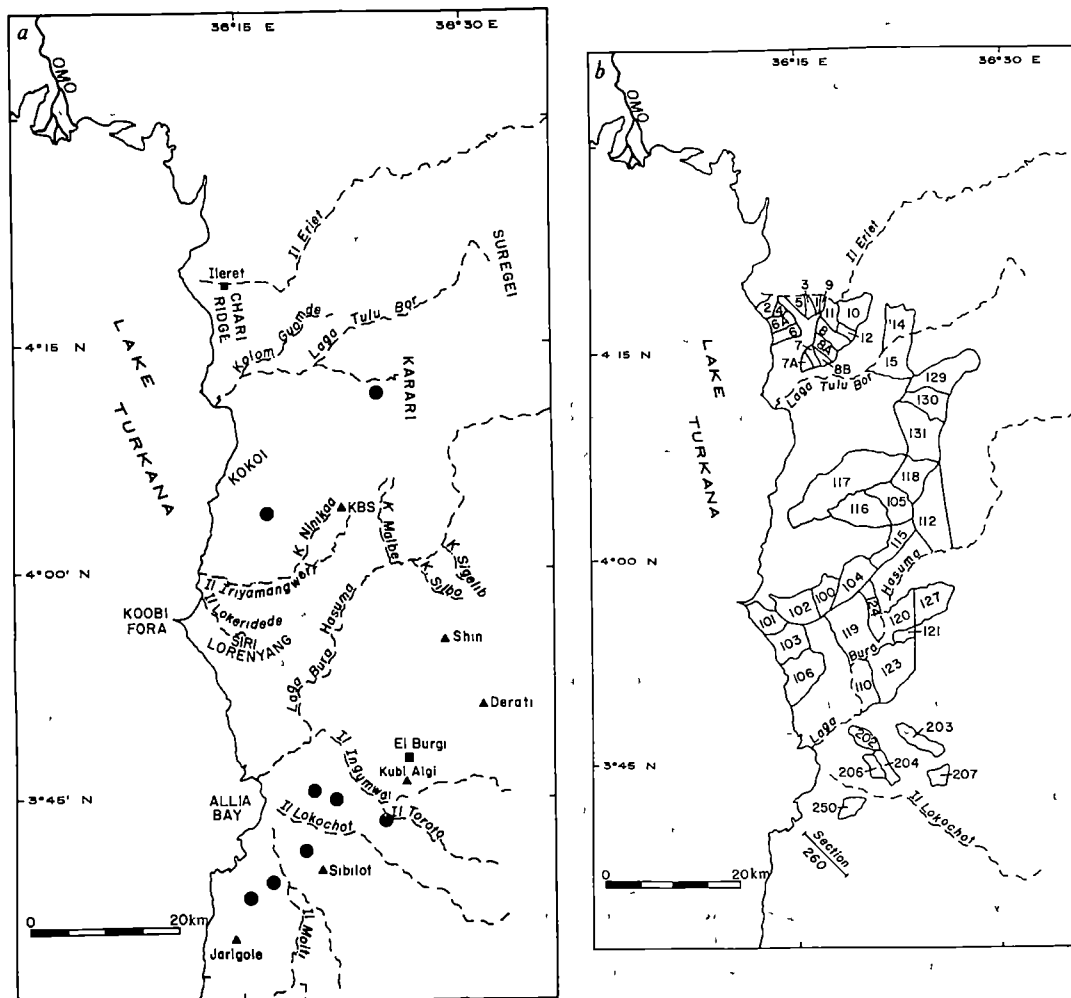

The three Plio-Pleistocene formations were defined using the Suregei, Tulu Bor, KBS and Chari Tuffs either as defining horizons or as horizons useful for correlation from one part of the basin to another. The Kubi Algi Formation (the oldest) was defined as "those strata that lie below the basal contact of the Suregei Tuff Complex"¹. The Koobi Fora Formation was defined as "those sedimentary strata which lie between the basal contact of the Suregei Tuff Complex and the upper contact of the prominent tuff exposed along the Ileret ridge, here named the Chari Tuff, or the basal contact of the Holocene gray tuffaceous predominantly lacustrine siltstones which represent a late stage rise in the level of Lake Rudolf"¹. The Guomde Formation was defined as "those strata which lie between the top of the Chari Tuff on the Ileret ridge and the overlying gray tuffaceous siltstones which represent a late stage rise in the lake level"¹. To understand clearly what is meant by the stratigraphy, we must determine what was meant by each of the marker beds when the formations were defined.

Suregei Tuff Complex: What was originally referred to as the Suregei Tuff Complex has recently been called the Suregei Diatomite Complex⁸ following demonstration that the Suregei Tuff Complex is not tuffaceous². Most of the diatoms in this unit are recrystallized, however, and therefore we refer to this unit as the Suregei Complex. Bowen and Vondra¹ state that

Fig. 1 *a*, Map of the Koobi Fora Formation region showing names of principal geographical features ●, Points at which the Tula Bor Tuff has been positively identified *b*, Map of the Koobi Fora Formation region showing palaeontological collection areas

this complex "extends from immediately east of the Ileret area to about 15 km to the south along the Suregei". Thus the type area lies within areas 14 and 15 (Fig 1*b*), and the complex takes its name from the Suregei highlands. In this area the Suregei Complex consists of pale tan to pale grey siltstones and claystones with prominent white bands which contain cristobalite. This unit lies about 80 m below the Tulu Bor Tuff near the boundary between area 15 and area 129 (ref 12).

Tulu Bor Tuff: The type area of the Tulu Bor Tuff lies in what is now area 129. Vondra and Bowen¹⁴ state that the Tulu Bor Tuff "outcrops extensively between the Laga Tulu Bor and the southern margin of the Kokoi". This tuff is light grey, and most of the shards are flat bubble-wall fragments. It contains a variety of sedimentary structures including parallel lamination and cross-bedding. Occasionally it contains lenses of small pumice pebbles. In the southern part of the Koobi Fora region it is generally ~10 m thick, whereas in the north it is only ~3 m thick.

KBS Tuff: The type locality of the KBS Tuff is unequivocal. It is a tuff exposed at the KBS archaeological site, a location clearly marked on Fig 1 of ref 11 in what is now area 105. This tuff is light grey, and consists of medium to fine glass shards ~10–30% of which are usually brown, often giving the tuff a salt-and-pepper appearance, although sometimes the basal portion has only clear shards. In many localities the tuff contains pumice clasts up to 30 cm in diameter. The thickness of this bed is variable but generally approximates 1 m, in many areas it is absent.

Chari Tuff: Bowen and Vondra¹ define this tuff as a prominent tuff exposed along the Ileret Ridge, however, there is more than one prominent tuff along the Ileret Ridge. We propose that the prominent tuff exposed in area 5 be regarded as the

type locality of the Chari Tuff. It is light grey, and consists of fine to medium glass shards, with elongate tubules. The Chari Tuff is 1–2 m thick, often has a tuffaceous clay layer at the base, and is thinly bedded at the base and top. In most exposures it contains pumice clasts which may be up to 50 cm in diameter.

In addition to these marker beds, it will be necessary to use names of two other beds in the Koobi Fora region, the Allia Tuff (or 4/5 tuff) and the Hasuma Tuff (or 3/9 tuff), both of which were defined by Findlater¹⁷. It will also be convenient to refer to the Lokochot Tuff and Ingumwai Tuff, which are defined in ref 19.

Correlation methods and analytical procedures

Bowen and Vondra¹ correlated three marker beds from the northern part of the region to other parts of the basin on the basis of internal stratigraphical consistency. From lowest to highest these levels were (1) the Suregei Tuff, recognized by its white colour and fine grained nature, and by the fact that the enclosing sediments were silty claystones, (2) the Tulu Bor Tuff, recognized by its distance 80 m above the Suregei Tuff and by its 3 m thickness, and (3) the KBS Tuff, recognized by its 30 m distance above the Tulu Bor Tuff, its fluvial nature, its position several metres above the highest beds of laminated siltstone facies, and its 'salt-and-pepper' appearance. These horizons were originally recognized in the northern part of the Koobi Fora region, later three similar horizons in area 102 were correlated with them. Additional support for the correlation of the Tulu Bor Tuff from area 129 to area 102 was provided by oxygen isotope analyses²⁰, although other proposed correlations were negated by the same data.

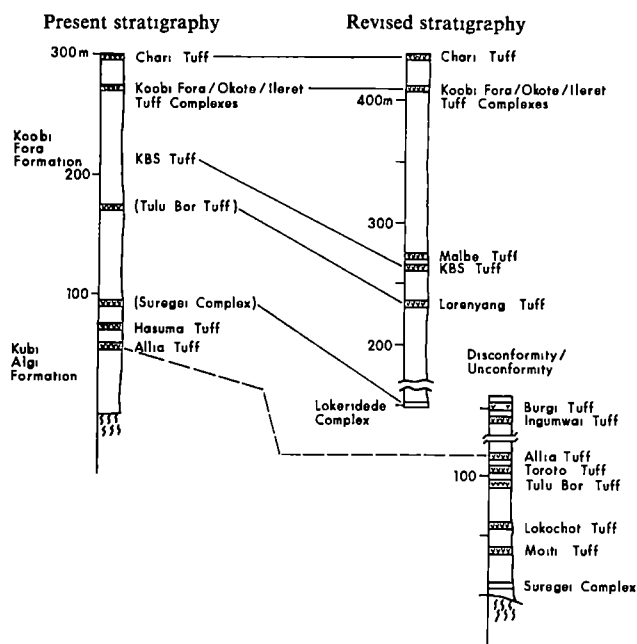

Fig. 2 Comparison of existing and revised stratigraphical nomenclature of Plio-Pleistocene sediments of the Koobi Fora region. See ref. 19 for additional discussion.

Our approach to stratigraphical correlation in the Koobi Fora region is based on chemical characterization of the tuffs, a method used successfully in many other studies²¹⁻²³. In many cases tuffs of the Koobi Fora region are very impure, sometimes consisting of only 10–20% glass shards. Bulk analyses yield meaningless results for purposes of correlation, and early attempts at using this method were discouraging²⁴. For this reason, we produced glass separates from the tuffs using heavy liquids and magnetic separation, calcite was removed with 10% HNO₃, clay films and limonitic staining were removed with 5% HF in conjunction with ultrasonic vibration. Each sample was checked optically to ensure that the separates consisted of >99% glass before analysis. In general the only remaining impurities in the glass were minute feldspar microlites in the shards.

The samples were analysed by X-ray fluorescence techniques on pressed pellets of the glass mixed with cellulose in a 4:1 ratio. Because these tuffs are alkaline or possibly peralkaline²⁵, they are rather different in trace element chemistry from most standard rocks. Two samples were analysed by the standard addition method, and were then used as standards for determination of Nb, Zr, Y, Sr, Rb and Zn on all other samples. Absorption corrections for these elements were made using the reciprocal of background. Analyses for Ti and Ba were made using United States Geological Survey standard G-2, correction for absorption was made using a regression based on potassium content. Iron and manganese were determined colorimetrically on a series of samples spanning the total range of concentration observed; other samples were analysed by X-ray fluorescence for these elements using the colorimetrically analysed samples as standards. Absorption corrections for iron and manganese were estimated by determination of absorption of CrK β . Precision and accuracy for all elements except barium are estimated to be ~2% and 5%, respectively, barium values are within 10% except those below 100 p.p.m., when the values are ± 25 p.p.m.

Our method of correlation depends primarily on the ability to recognize tuffs which are chemically distinct, rather than on the character of the sediments which enclose the tuffs. We have described problems which might be encountered in this method of correlation in a separate paper²⁶. Here only analyses of the Tulu Bor Tuff and tuffs formerly correlated with the Tulu Bor Tuff are presented (Table 1). However, analyses of more than

200 samples of some 30 distinct tuffs from the region are consistent with the correlations proposed below, and none of our correlations are inconsistent with correlations which might be made from stratigraphical considerations, although they differ from those proposed by earlier workers.

Identification of the Tulu Bor Tuff does not rest on analyses of that unit alone. In both the northern and southern part of the region the Lokochot Tuff¹⁹ underlies the Tulu Bor Tuff. The Tulu Bor Tuff and the Lokochot Tuff are correlative with Tuffs B and A of the Shungura Formation, respectively¹⁹.

Distribution of the Tulu Bor Tuff

We have analysed the Tulu Bor Tuff in area 129, its type locality, in area 117, and in areas 204, 207 and section 260 where it had not been previously recognized. We have also analysed samples of what was said to be the Tulu Bor Tuff in areas 15, 102, 110 and 116. The tuffs in areas 15, 102, 110 and 116 which were thought to be the Tulu Bor are not.

The tuff described as the Tulu Bor Tuff in area 102 is here named the Lorenyang Tuff after the local name for part of the Koobi Fora Ridge (Siri Lorenyang). The type locality of this tuff is in area 102, where it is best exposed in the centre of an anticline located in the north central part of the area. Here it is 3 m thick, is grey, fine grained, contains disrupted small scale cross-beds and has a sharp basal contact with a gradational upper one. The shards are frothy and quite distinct from the flat shards of the Tulu Bor Tuff. It also occurs in area 104, where it had been mapped¹⁸ as the KBS Tuff.

The tuff previously mapped as the Tulu Bor Tuff in area 110 is the KBS Tuff. This is sensible as the section above it is very similar to the section above the KBS Tuff in area 102.

The tuff in area 116 is the source of material dated at 3.18 Myr (ref. 27), a number generally associated with the Tulu Bor Tuff. This tuff is the uppermost of three tuffs in a continuous section ~10 m thick, and is here designated the Nimikaa Tuff. It consists of medium to fine cross-bedded grey ash and contains pumice clasts up to 20 cm in diameter. About 30% of the shards are brown, and shard shapes include bubble junction, stretched and frothy types. It appears to be confined to a channel.

The stratigraphical position of the Nimikaa Tuff has not been satisfactorily determined, however, it is very similar in composition to one sample of a tuff mapped as the Hasuma Tuff¹⁵. At least two different tuffs have been mapped as the Hasuma Tuff, and stratigraphical relations between these have not been determined. The particular sample similar to the Nimikaa Tuff lies ~25 m above the Tulu Bor Tuff in area 204.

Significance of the distribution of the Tulu Bor Tuff

Bowen¹² places the Suregei Complex about 80 m below the Tulu Bor Tuff in his section 130-1 along the western margin of the Suregei Cuesta. Findlater¹⁵ places the Allia Tuff 74 m below what Bowen and Vondra¹ identified as the Suregei Complex in areas 202 and 204. Acuff²⁸ finds a different thickness, but agrees on the stratigraphical order. We were therefore surprised to find that the Tulu Bor Tuff lies stratigraphically below the Allia Tuff in areas 204 and 207, and therefore must also underlie the so-called Suregei Complex of area 202. As the Suregei Complex lies below the Tulu Bor Tuff in the type area of both units, it is evident that the unit mapped as the Suregei Complex in area 202 must be a different stratigraphical horizon from that in area 15. Thus two different stratigraphical horizons have been correlated and mapped as the Suregei Complex. One of these lies near the base of the Plio-Pleistocene sequence in the Koobi Fora region, the other is much younger and lies nearer the middle of the sequence.

In order that these two units no longer be confused, we designate the white siltstones in area 102 as the Lokeridede

Complex, after the name of a small stream nearby. This unit lies below a major topographical break in slope and thus lies below the well exposed section in area 102. The nature of the contact is obscure, but the trend of the Lokeridede Complex differs from that of the overlying sediments, suggesting that it may lie below a slight angular unconformity. We accept the correlation of Williamson⁷ of this unit with the unit designated 'Suregei Tuff Complex' in area 202 because it seems to be situated in roughly the same position with respect to the KBS Tuff in area 110, and is lithologically similar. This complex is at about the level of the Burgi Tuff which is defined in the accompanying article. This unit is a very light grey montmorillonitic claystone containing cristobalite with parallel bedding. It is saline, with gypsum at the surface, and contains abundant recrystallized diatoms.

The base of the Suregei Complex is defined as the base of the Koobi Fora Formation. What has been erroneously identified as the Suregei Complex in area 202, however, overlies the Tulu Bor Tuff, furthermore, the Tulu Bor Tuff is widely exposed in what has been mapped as the Kubi Algi Formation, but in its type area belongs to the Koobi Fora Formation. Here a choice must be made, either the Koobi Fora Formation and the Kubi Algi Formation must be redefined, or the Kubi Algi Formation must be regarded as a very small part of the sedimentary sequence in the Koobi Fora region. At present we leave the definitions of the formations as they are, and apply those definitions throughout the Koobi Fora region—strata everywhere in the region which lie between the Suregei Complex and the Chari Tuff must be assigned to the Koobi Fora Formation.

Although we have not redefined the Koobi Fora Formation, certain strata formerly placed in the Kubi Algi Formation are now assigned to the Koobi Fora Formation. Figure 2 shows a composite section of the Koobi Fora Formation in which the old stratigraphical nomenclature is compared with the revised nomenclature. Stratigraphical terms in parentheses are formerly named units which were miscorrelated from their type localities. Stratigraphical thicknesses shown on the revised diagram are only our best estimates at present.

Discussion and conclusions

The most important implication of this work is that the type section of the Koobi Fora Formation includes neither of the marker horizons which were used to define the formation. The present type section begins at the Lokeridede Complex, not the Suregei Complex, and extends upward to levels above the Koobi Fora Tuff Complex, but not to the Chari Tuff. The

existing type section near the Koobi Fora spit requires correction, because the interval between the KBS Tuff and the Koobi Fora Tuff Complex (shown as ~80 m)¹⁴ is far too thin, and must be increased by nearly a factor of two^{2,29}. New sections which extend the present type section of the Koobi Fora Formation must be established which include the defining marker beds. It may be desirable to redefine the Koobi Fora Formation when such sections are established so that it includes the small sections below the Suregei Complex and above the Chari Tuff. As defined at present, the Kubi Algi Formation is only ~5 m thick, and is not lithologically distinct from the strata immediately above the Suregei Complex, thus there is no good reason for retaining that formation as a stratigraphical unit. Similarly, most of those strata presently assigned to the Guomde Formation should be included as part of the Koobi Fora Formation, because the two formations are not lithologically distinct². Strata belonging to the Guomde Formation as presently defined¹ have been mapped as part of the Upper Member of the Koobi Fora Formation in one area, and as part of the lower member of the Koobi Fora Formation in others^{12,15}.

The stratigraphical revisions proposed above are based solely on tuff correlation, but many of the same revisions, or variations on them, were proposed independently on the basis of palaeontological considerations^{4,6,7}. With the proposed revisions, most faunal correlation problems disappear without having to call on ecological differences to explain them. Fossil mammal assemblages in the Turkana basin appear, indeed, primarily to reflect age, as noted earlier³⁰, ecological effects seem subordinate.

Mapping, palaeomagnetic interpretations, definition of isotopic trends of carbonates and volcanic glass in time, and palaeogeographical reconstructions^{8,14,31} are all dependent on the lithostratigraphy, and earlier studies in these areas will have to be reconsidered (or amended). Although the revisions proposed above are important to the geological history of the area, the geographical positions of invertebrate and mammalian (and hominid) fossil specimens are not affected, and since they are recorded on aerial photographs³², their stratigraphical attributions can be checked. The Koobi Fora region is well known for its fossil hominids, but as most of these come from levels near or above the KBS Tuff, the present revisions will affect few of them.

We thank R. E. Leakey, M. G. Leakey and G. L. Isaac for support, J. M. Harris and P. Williamson for critically reading the manuscript, B. E. Bowen for copies of his field notes, B. W. Cerling, D. Norman and T. Haig for sample preparation, and P. Onstott for drafting the figures. Principal financial support of this work was provided by the NSF, grant BNS-8007354. We also acknowledge support from grant BNS-80-14139, and the National Museums of Kenya.

Tuffaceous marker horizons in the Koobi Fora region and the Lower Omo Valley

T. E. Cerling & F. H. Brown

Department of Geology and Geophysics, University of Utah, Salt Lake City, Utah 84112, USA

Eight tuffs can now be correlated between the Shungura Formation in the Lower Omo Valley, Ethiopia, and the sediments in the Koobi Fora region, Kenya. Re-evaluation of the stratigraphy shows that at least 475 m of sediment was deposited in the Koobi Fora region

BOTH the Lower Omo Valley, Ethiopia, and the Koobi Fora region, Kenya, have been extensively studied geologically, and for their mammalian remains¹⁻³, we now consider the correlation of tuffs in Plio-Pleistocene strata. The Shungura Formation in the Lower Omo Valley is a sequence of fluvial and lacustrine sediments deposited by the proto-Omo River which drained the Ethiopian highlands. Its good exposure and relatively simple stratigraphy have resulted in a well-calibrated Plio-Pleistocene section. This 760-m thick section ranges in age from ~3.5 to ~0.8 Myr in age⁴. Twelve members have been recognized and are defined on the basis of widespread tuffs, labelled A to L from the lowest to the highest member. In addition to the tuffs used to define members, >100 other tuffs have been recognized in the section.

Plio-Pleistocene strata in the Koobi Fora region are only slightly tilted, and have fewer long stratigraphical sequences

exposed than does the Lower Omo Valley. Large areas of late Quaternary alluvium separate exposures of the Plio-Pleistocene strata. These strata appear to have had a more complicated erosional history that has resulted in discontinuities in the section. However, the Plio-Pleistocene strata in the Koobi Fora region span approximately the same time interval as those in the Lower Omo Valley. The Plio-Pleistocene strata of the Koobi Fora region have been divided into the Kubi Algi, Koobi Fora and Guomde Formations in stratigraphical order from oldest to youngest^{5,6}. Of these formations, only the Koobi Fora Formation has been studied in detail⁵⁻¹⁴.

Procedure

Samples from the Shungura Formation were collected in 1972-74, most samples from the Koobi Fora region were collected from 1977 to 1981, although a few were collected earlier.

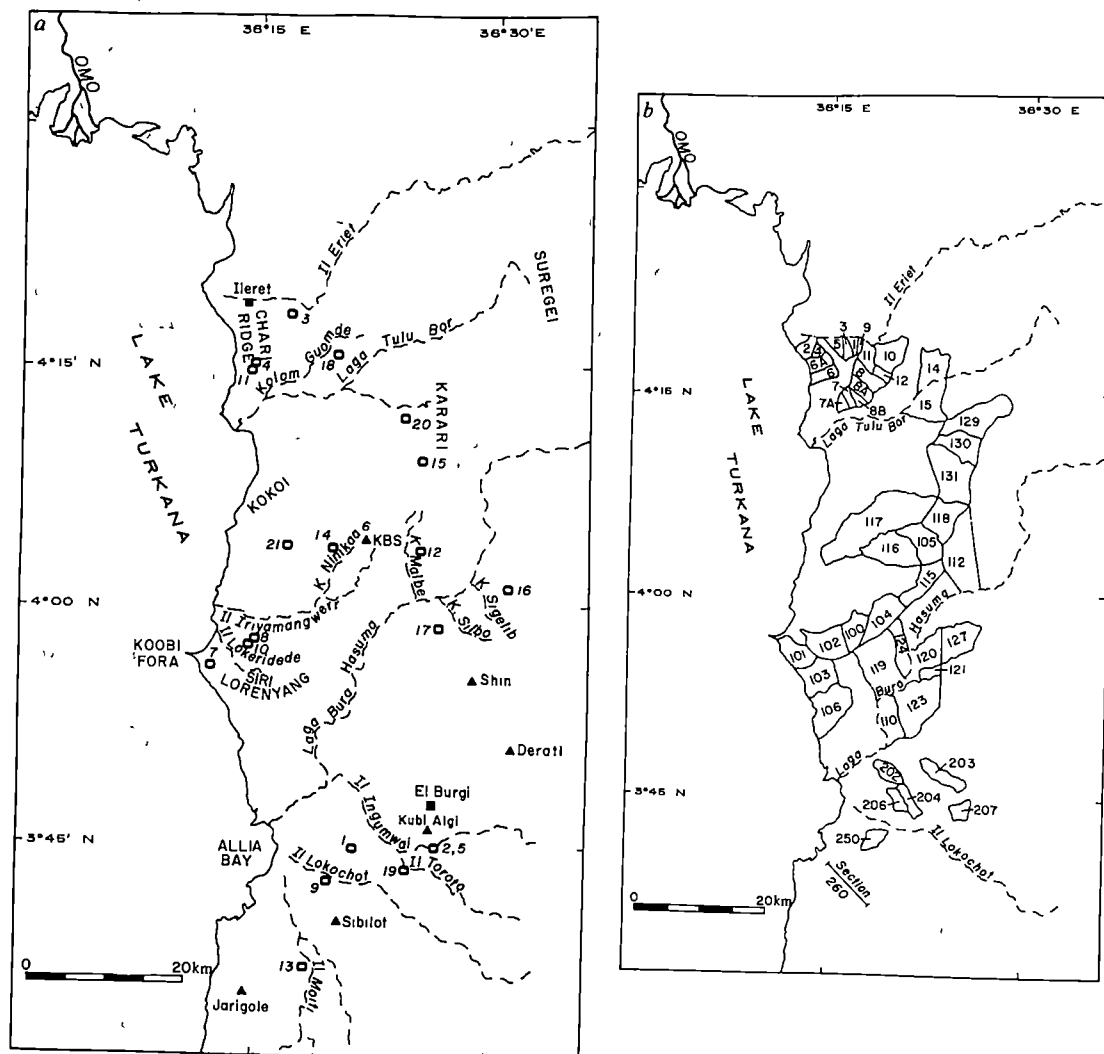

Fig. 1 a, Geographical localities in Koobi Fora region. Numbers refer to type localities of marker horizons (Table 3). b, Fossil collection areas.

* 15 m below Allia Tuff (77-31)

† Allia Tuff of Findlater^{7,9}

‡ Pumice

§ Analysis by electron microscope

|| Previously mapped as Surgaei Tuff^{7,9}¶ Previously mapped as Tulu Bor Tuff^{7,9}

Composite pumice sample. Previously unmapped as any tuff

** Previously mapped as KBS Tuff^{7,9}†† Previously mapped as Chari Tuff^{7,9}‡‡ Previously mapped as Okote Tuff^{7,9}

Samples were prepared and analysed as described in ref 15. New standards more similar in composition to our samples than the USGS rock standards have resulted in analytical results that are more accurate and more precise than those reported earlier¹⁶. Where statements are made concerning individual shards, the analyses were done by electron microprobe.

Results

Eight pairs of horizons in the two regions can be correlated on the basis of chemical compositions (Table 1). Tuffs A, B- α , B- β , C4, H2, H4, J7 and L from the Lower Omo Valley correspond to the Lokochot Tuff, the α -Tulu Bor Tuff, the β -Tulu Bor Tuff, the Ingumwai Tuff, the KBS Tuff, the Malbe Tuff, an unnamed tuff near the level of the Koobi Fora Tuff, and the Chari Tuff in the Koobi Fora region, respectively. These correlations together with definitions of new tuff names and complications are discussed below.

Tuff A-Lokochot Tuff: Tuff A is the lowest major tuff in the Shungura Formation, situated ~30 m above the lowest exposed sediments of the Shungura Formation. The Lokochot Tuff, in the Koobi Fora region, is named for a major ephemeral

stream channel, Il Lokochot, in the area east of Allia Bay, this tuff crops out extensively in this region and is also exposed in area 117, south of the Kokoi (see Fig 1 for area designations and geographical names). The type exposure is located 200 m west of the point where the road crosses Il Lokochot. Here, the Lokochot Tuff is a 2.0-m thick bed of poorly stratified, grey, coarse to medium ash, with calcified rootcasts in its lower part. The glass shards are very light grey and clear or slightly frosted, they are stretched, bubblewall and platey shards. This tuff rests on a bed of greyish brown silty claystone with polyhedral fracture, irregular subvertical carbonate fillings occur in the upper part of the silty claystone. It is overlain by sandy siltstones and clayey siltstones. The strata in which it is located were formerly assigned to the Kubi Algi Formation⁵⁻¹⁴, although we believe that these beds should be assigned to the Koobi Fora Formation¹⁵. Analysis of glass separates (Table 1) from Tuff A and from the Lokochot Tuff are indistinguishable. This tuff is of interest because analyses of individual shards by electron microprobe fall into two distinct compositional groups (Fig 2), both of which differ from the bulk composition of the glass separates. Tuff A also has this characteristic. It is possible

Table 2 Representative chemical analyses of some trace and minor elements from pure glass separates from marker tuffs at their type localities (see Table 3) in the Koobi Fora region

Only one analysis is given for each tuff unless additional analyses of pure glass separates from the tuff showed compositional variability. Concentration is given in parts per million, except calcium and iron which are reported as the oxide in per cent. Total iron as Fe₂O₃.

that two tuffs erupted at different times may have very similar compositions, but the unique combination of finding two tuffs with identical bulk analyses and having two shard compositions mixed in the same ratio is very unlikely to have happened twice. Consequently, we regard the correlation of Tuff A and the Lokochot Tuff as one of the strongest ties between the Shungura Formation and the Plio-Pleistocene strata at Koobi Fora.

Tuff B-Tulu Bor Tuff: Tuff B of the Shungura Formation was divided into several units when it became clear that it represented several depositional events. We have analysed glass separates from tuffs from only the lowest two units, Tuff B- α and Tuff B- β . Although they differ slightly in composition they are chemically related (Table 1).

Several different stratigraphical horizons have been called the Tulu Bor Tuff⁵. Here, we use this name only for the tuff in area 129 (where it was originally named), and for those tuffs that have similar or indistinguishable compositions. The Tulu Bor Tuff in the Koobi Fora region has at least two variants, two of these correspond to Tuff B- α and Tuff B- β of the Shungura Formation (Table 1), and we refer to these as the α -Tulu Bor Tuff and β -Tulu Bor Tuff, respectively. Where a distinction is not necessary the term Tulu Bor Tuff is used. The type Tulu Bor Tuff in area 129 corresponds to Tuff B- α of the Shungura Formation (Table 1), this tuff is also found in areas 117, 204, 207 and 260. The tuff mapped as the Tulu Bor Tuff in area 117 (refs 8, 10) is in most places equivalent to Tuff B- β of the Shungura Formation (Table 1). However, in area 117 ~10% of the shards are compositionally similar to those of

the α -Tulu Bor Tuff, indicating that it has some older shards reworked into it.

In addition to the compositional similarity there are several other favourable points of comparison between Tulu Bor Tuff and Tuff B. Both are of normal polarity^{4,16}, and composed dominantly of flat bubble wall shards. The Tulu Bor Tuff lies ~35 m above the Lokochot Tuff, a distance comparable with the 40 m that separates Tuff B from Tuff A in the Shungura Formation. The intervening section of fluvial sediments is also similar.

Tuff C4-Ingumwai Tuff: Tuff C4 in the Shungura Formation lying ~110 m above Tuff B has normal polarity. Table 1 shows that sample K80-273 is chemically similar to Tuff C4. This is a sample of the lowest of four tuffs exposed in a cliff along Il Ingumwai (Fig. 1a). At this locality it lies ~50 m above the Tulu Bor Tuff. This tuff is here defined as the Ingumwai Tuff. It has a maximum thickness of ~0.5 m in this exposure, and is lenticular, pinching out to the west. It is pinkish grey to very pale yellowish grey, and consists of silt to medium sand sized glass shards. Most shards are light grey to greyish white, a few are very light brown. They are generally frosted. Most are stretched or frothy.

Tuff H2-KBS Tuff: Tuff H2 of the Shungura Formation has previously¹⁷ been correlated with the KBS Tuff in the Koobi Fora region on the basis of trace and minor element contents of glass separates from pumice, compositions of phenocrysts in pumice, and on the major and minor element content of glass shards analysed by the electron microprobe. We have since analysed glass separates from tuffs by X-ray fluorescence, and can now positively identify the KBS tuff in areas 10, 15, 130, 131, 105, 110 and south of area 106 (Table 1). Glass shards from the KBS Tuff are fairly distinctive. In general, the shards are clear 60–90% are very light grey or colourless. The remainder grade from light grey to dark brown. This gives the tuff a 'salt-and-pepper' appearance in many localities. Occasionally the basal portion does not have the dark shards, Tuff H2 also lacks dark shards. The shards are a subequal mixture of bubble-wall stretched, platy and frothy types. Occasionally this tuff has <30% glass and should properly be called a tuffaceous sandstone (for example, area 102). Chemical analysis by electron microprobe indicates its presence in area 102 (ref. 17). The samples from area 110 and south of area 106 are from tuffs which had previously been mapped as the Tulu Bor Tuff and the Suregei Tuff, respectively^{7,9}, other tuffs mapped as the KBS Tuff can be shown to be different on the basis of their chemistries (see discussion below). Both Tuff H2 and the KBS Tuff lie in sections of normal polarity^{4,17}, the KBS Tuff has

Fig. 2 Iron and titanium contents of individual glass shards from *a*, the Lokochot Tuff (59 shards) and *b*, from Tuff A (30 shards). Each point represents the average composition of an individual shard.

been dated at 1.89 ± 0.02 Myr (samples from areas 105 and 131 in ref 19), a date comparable with that of Tuff H2 (1.88 Myr).

Tuff H4-Malbe Tuff: Tuff H4 occurs 15 m above Tuff H2 in the Shungura Formation. Tuff H4 has previously¹⁷ been correlated with a tuff in the Koobi Fora region, which we now designate as the Malbe Tuff, named for Kolom Malbe, along which this tuff is well exposed. This tuff occurs ~15 m above the KBS Tuff in the eastern portion of area 105. Analyses of glass separates from this tuff are given in Table 1. This tuff has pumice clasts of variable composition, which are not included in Table 1, but which are discussed elsewhere^{17,18}. Glass separates from these pumices fall on a single compositional trend, and may represent eruptive products of different portions of a compositionally variable magma chamber¹⁸. Electron microprobe studies of individual shards show that the entire range of glass compositions spanned by the pumice glasses is present in the tuff¹⁸. Although McDougall *et al.*¹⁹ do not distinguish this tuff from the KBS Tuff, samples of this tuff give a K/Ar age of 1.88 ± 0.02 Myr (samples from area 112 of ref 19).

In its type area the Malbe Tuff is confined to a channel, and reaches a maximum thickness of ~2 m. It can be distinguished from the KBS Tuff in the field wherever it contains pumice, because the pumice clasts of the Malbe tuff are an assemblage of very dark brown (nearly black), medium grey and white types, whereas those of the KBS Tuff are dominantly grey or white, with very rare (<1%) dark pumice.

Tuff J7-Koobi Fora Tuff (*sensu lato*): Tuff J7 of the Shungura Formation occurs in sediments of reversed polarity. An unnamed tuff in area 119 (K80-195) has essentially the same composition as Tuff J7 (Table 1). This tuff is at about the same level as the Koobi Fora Tuff, which also has reversed polarity¹⁶. This sample is ~5 m below a tuff which is compositionally the same as a sample from the Koobi Fora Tuff in area 101.

The Ileret Tuff Complex, the Okote Tuff Complex and the Koobi Fora Complex, or variations on these names, are found near Ileret, along the Karari Ridge and near Koobi Fora spit, respectively. These tuffs have been correlated^{9,10} because they are tuffaceous intervals above the KBS Tuff. We have analysed over 30 glass separates from pumice and tuffs from these localities and have found only one compositionally distinct set of samples. They are found at the base of the Ileret Tuff

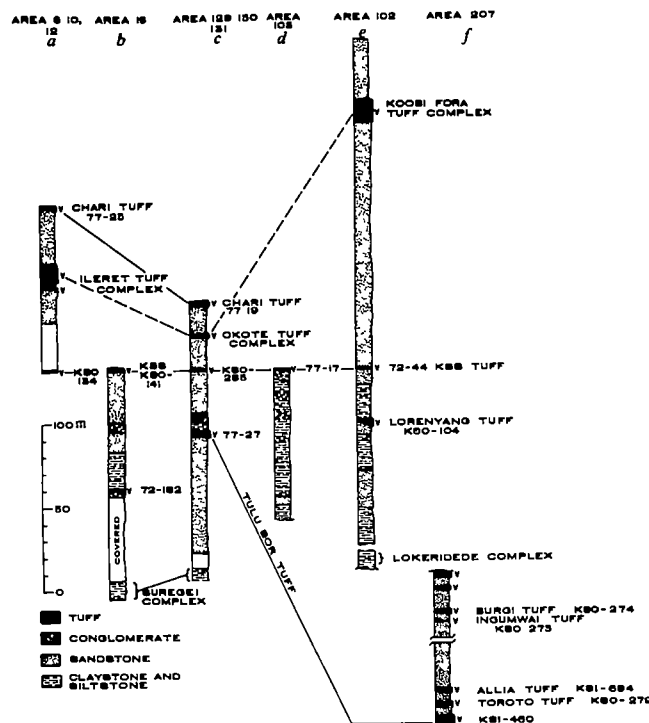

Fig. 3 Stratigraphical sections of Plio-Pleistocene sediments in the Koobi Fora region. Section a by Bowen⁵ and T E C, section b by Bowen⁵, section c by Bowen⁵ and T E C, section d by T E C, section e by T E C, section f by F H B and T E C.

Complex. Thus, we designate this tuff as a separate unit, the Lower Ileret Tuff. This tuff is medium to dark grey, has fine to medium shards, and is ~1 m thick. The shards are dark grey and are dominantly frothy. It has an abrupt basal contact and overlies a brown mudstone with prismatic structure. It is overlain by 3–4 m of interbedded sandstones and siltstones, which give way to the tuffaceous sand and silts of the Ileret Tuff Complex.

The Ileret, Koobi Fora and Okote Tuff Complexes have variable chemistries as shown by major, minor and trace element analyses of glass separates from pumice and from tuff

Representative compositions of tuffs from the type locality are given in Table 2. Other names that have been used for these horizons in their type localities are also included. The type localities are shown in Fig. 1.

* Localities are given by coordinates of type locality on 9×9-inch photographic prints of area taken in December 1970 by Hunting Surveys, London. X and Y coordinates are in millimetres from the left edge and from the top edge of print, respectively.

† Contains diatoms. Probably recrystallized diatomite.

‡ Captions for Figs 3 and 5 in ref. 8 are transposed.

Fig. 4 Correlations of marker horizons in the Koobi Fora region with those in the Shungura Formation. Revised total thickness based on section *a*, *e* and *f* of Fig. 3. Sediment thickness above the Chari Tuff and stratigraphical positions of the Lokochot and Moiti Tuff are based on unpublished field notes. The Ninikaa Tuff occurs about 25 m above the Tulu Bor Tuff, the Lokeridede Complex lies at about the level of the Burgi Tuff, the position of the Sigelb Tuff is not yet known.

Electron microprobe studies of individual shards from each of these tuff complexes show that each tuff is heterogeneous. The X-ray fluorescence and electron microprobe studies both suggest that all samples are genetically related in that the variations fall on well defined compositional trends. Thus, we feel that although these tuffs complexes are of about the same age, they should be considered as three separate units. In no case can one show that any individual subunits from two different complexes are correlative. These complexes are equivalent in age to upper Member J and Member K of the Shungura Formation. The distinction between correlation of these as general units versus as individual beds is important. If the time-mesh required for a particular study is on the order of 10,000–100,000 Myr, they can be considered as correlative. However, if a study requires a more narrow time-mesh (for example, a palaeoecological studies), then they cannot be considered to be time-stratigraphical units. We hope that we will soon be able to define more finely the relationship between the Ileret, Okote and Koobi Fora Tuff Complexes. Until then, they should retain their distinctive names.

Tuff L–Chari Tuff: Tuff L of the Shungura Formation has previously¹⁷ been correlated with the Chari Tuff of the Koobi Fora Formation, and the Chari Tuff was thought to be the same as the Karari Tuff of Findlater^{7,9} (see Table 1). Since the name Chari Tuff has precedence over the name Karari Tuff, only the former name should be retained.

Other tuffs

In addition to these tuffs, there are other tuffs which are fairly widespread, or of importance because they have been dated. Some of these were previously thought to be the Tulu Bor Tuff,

but in an accompanying article, we show that previous correlations of the Tulu Bor Tuff to areas 15, 102, 110 and 116 are in error¹⁵. One of these is the KBS Tuff (area 110). The Tuff in area 15 remains unnamed, the tuff in area 102 has been named the Lorenyang Tuff¹⁵. The tuff in area 116 is of importance because it has been dated by K/Ar at ~3.1 Myr (ref. 20 and G. H. Curtis, unpublished data) and has been named the Ninikaa Tuff¹⁵.

In the southern part of area 204, where the Allia Tuff was mapped^{7,9}, there are three tuffs in ~15 m of section. The uppermost tuff is the most prominent, and its outcrop pattern corresponds most closely to the Allia Tuff on these maps^{7,9}, therefore we have assigned it the name Allia Tuff. The lowest tuff in this sequence is the Tulu Bor Tuff (Table 1), the intermediate tuff in this sequence is here named the Toroto Tuff. These three tuffs are quite distinctive and descriptions of the Toroto and Allia Tuffs are given below, the Tulu Bor Tuff is described in the accompanying article¹⁵.

The Toroto Tuff takes its name from Il Toroto, a tributary stream to Il Ingumwai. It is dark grey tuff ~2.3 m thick with conspicuous pumice clasts in its upper part. The lower part (0.8 m) is an impure tuff with many flat glass shards of fine to coarse sand size.

The Allia Tuff is a massive 2-m thick tuff in area 204, the uppermost of three tuffs in a 15-m stratigraphical interval. It is white, the glass shards are coarse to medium in grain size and are predominantly stretched in shape. They are similar to the stretched variety of shards observed in the Koobi Fora Tuff, but the walls of the tubules are more massive in the Allia Tuff.

The Moiti Tuff outcrops extensively in the southern part of the sedimentary sequence in the Koobi Fora region. It is the lowest of five widespread tuffs in the Allia Bay region, which are the Allia, Toroto, Tulu Bor, Lokochot and Moiti Tuffs, in descending order. It is ~20 m below the Lokochot Tuff. The tuff is medium grained, has bubble-junction shards and sometimes contains pumice up to 20 cm in diameter. Locally it is extremely pure. The pure basal portion is from 0 to 50 cm in thickness and is overlain by up to 5 m of impure tuff.

The Burgi Tuff occurs ~5 m above the Ingumwai Tuff along Il Ingumwai near Kubi Algi. It takes its name from a waterhole, El Burgi, ~3 km north of Kubi Algi. It is the lower of two tuffs of similar composition, these two tuffs are found in several localities south and east of Laga Bura Hasuma. The Burgi Tuff is ~1 m thick in its type locality, the shards are light grey and are predominantly stretched, although a few frothy shards are also present. In area 202 it occurs just below the level of a Zone 3 molluscan fauna of Williamson²¹, in area 102 the Lokeridede Complex occurs above a Zone 3 molluscan fauna²¹. Thus the Burgi Tuff lies near the level of the Lokeridede Complex.

The Silbo Tuff refers to a tuff whose type area is near Shin, just south of Kolom Silbo for which it is named. It is also exposed in area 7, and along the western margin of the Kokoi (Table 1). It has been variously mapped as the Chari, Okote, and KBS Tuffs^{7,9}, and lies within the Guomde Formation⁵. The Silbo Tuff is massive, up to 2 m thick, greyish white, and composed dominantly of stretched and bubble-wall shards. It often contains isolated pumice clasts up to 50 cm in diameter, in its type locality it has a pumice channel that has pumice clasts up to 100 cm in diameter.

The Sigelb Tuff is a massive, 6-m thick tuff that is exposed on the basin margin and was previously mapped as the KBS Tuff^{7,9}. It is dark grey, has medium to fine grained shards which are predominantly bubble-wall fragments or stretched varieties. Its age and stratigraphical position have not been established.

Discussion

We have analysed over 200 glass separates from tuffs in the Koobi Fora region. We have found more than 40 chemically distinct tuffs. We have also observed additional tuffs whose weathered aspect does not allow them to be purified. Thus, there are more than 40 tuffs in the Koobi Fora region. We have

also analysed numerous tuffs in the Shungura Formation, although we have done less than one-third of the total. There are now eight positive ties between the Koobi Fora region and the Lower Omo valley and more correlations are expected with analysis of additional samples from the Shungura Formation. Thus, many tuffs occur in both sequences, and approximately the same number of tuffs occur in any given interval in both sequences, contrary to earlier belief²².

If stratigraphical sections from different localities in the Koobi Fora region are examined in detail, several significant features are noted (Fig 3). In area 129, some 30 m of section separates the KBS Tuff (1.89 Myr in age¹⁹) and the Tulu Bor Tuff (> 3 Myr age⁴). In area 102, there is > 100 m of lacustrine section below the KBS Tuff; the Tulu Bor Tuff is not found in area 102. This lacustrine sequence (the laminated siltstone facies of Bowen^{5,11}) is about the same age and thickness as the lacustrine interval from G14 to G28 of the Shungura Formation, and so should be considered as broadly correlative, as suggested by Brown *et al.*²³ However, in area 207, south of Kubi Algi, ~70 m of section occurs above the Tulu Bor Tuff; these sediments are not similar to the laminated siltstones in area 102, but rather represent fining-upward fluvial cycles, and are in fact equivalent to members B and C of the Shungura Formation which is also characterized by fining-upward cycles. This suggests that a considerable thickness of sediment was deposited in the Koobi Fora region between Tulu Bor and KBS times.

However, in some areas (such as area 129) almost the entire thickness was removed before deposition of the KBS Tuff. In area 129, we believe that erosion exposed the Tulu Bor Tuff and that the present dip slope of the Tulu Bor Tuff may represent an exhumed land surface. In area 15, erosion probably removed the Tulu Bor tuff entirely. Based on correlation with the Shungura Formation, this erosion must have taken place between the time represented by member D and that represented lower part of member G, or between ~2.4 and ~2 Myr ago.

We can now account for much of the sediment thought to be missing in the Koobi Fora region²³. Stratigraphical thicknesses between marker beds in the Shungura Formation and the Koobi Fora Formation are often quite similar (Fig 4). This, combined with the presence of tuffs in both the Koobi Fora region and the Lower Omo Valley, implies that the two sequences were probably part of the same depositional system. Differences in thicknesses can sometimes be attributed to erosion, as well as to primary differences in thicknesses.

We thank B. W. Cerling and D. Norman for laboratory assistance, R. E. Leakey, M. G. Leakey and G. L. Isaac for support and encouragement, P. G. Williamson and J. M. Harris for critical comments on the manuscript, and B. E. Bowen for copies of his field notes. This work was supported by NSF grant no. BNS-8007354, the foundation for Research into the Origin of Man, and the National Museums of Kenya.

Eukaryotic ribosomes can recognize preproinsulin initiation codons irrespective of their position relative to the 5' end of mRNA

Peter T. Lomedico & Stephen J. McAndrew

Department of Molecular Genetics, Hoffmann-La Roche Inc., Nutley, New Jersey 07110, USA

The functional assay of a eukaryotic mRNA, into which additional AUG codons have been introduced by in vitro mutagenesis, shows that a translational initiation site need not necessarily be the nearest AUG codon to the 5' end of a mRNA. Hence, the sequence surrounding the AUG, and not simply its position relative to the 5' end of mRNA, appears to be important in determining initiation efficiency.

How does a ribosome decide where to begin translation on a eukaryotic messenger RNA? In prokaryotic mRNAs, initiation codons are preceded by a conserved, purine-rich sequence which plays some part in directing the ribosome to the correct AUG codon. In contrast, comparison of 5'-noncoding regions

of eukaryotic mRNAs fails to reveal any sequence homology or conservation, casting doubts on the existence of a sequence functionally analogous to the bacterial ribosome binding site¹. One simple hypothesis to explain initiation codon selection by the eukaryotic ribosome is that translation begins at the first

quences. The cloned deletion mutants were characterized by sequence analysis. The end point of each deletion is ample, the sequence across the *Hind*III site of mutant $\Delta 255$ and *Alu*I (403 bp) is TGCAAAAAGCTTGGCTACA, ion mutants were created by attaching *Hind*III linkers to *Hae*III (213 bp) fragments of pBR322, and inserting these. Individual clones were characterized by restriction analysis and the inserts were completely sequenced. The *Hae*III orientations in Apr12/SVO 255J2 (c) and Apr12/SVO 255J5 (d) and the *Alu*I fragment in one orientation, Apr12/SVO nows both *Hind*III sites (H), the preproinsulin initiation codon (boxed ATG), and the ATG triplets in the insert ity, the 5'-noncoding region intron is deleted (s denotes where this intron resides in the plasmid DNA), hence, e predicted sequence of the spliced mature mRNA. For convenience, these plasmids will be abbreviated as $\Delta 255J2$,

Fig. 2 Calcium phosphate DNA precipitate suspensions were formed²¹ using plasmid DNA at $20 \mu\text{g ml}^{-1}$ and presented to COS cells as described by Chu and Sharp²². One-fifth of the cells were plated in a 6-cm dish and the remainder in a 15-cm dish. Following a 5-h incubation at 37°C in 5% CO_2 , the DNA supernatant was removed and the cells were shocked with 25% glycerol in media for 1 min²², rinsed and returned to the incubator with fresh media. After 3 days, RNA was isolated from the 15-cm dish, and the cells in the 6-cm dish were labelled with ^{35}S -cysteine²³ for 4 h and solubilized with detergents²⁴. Equal amounts of solubilized proteins were reacted with antiserum to bovine insulin (Miles) in the presence (+) and absence (-) of an excess of bovine insulin (Sigma; $10 \mu\text{g}$) as competitor²⁵. The antigen-antibody complexes were recovered²⁶ using *Staphylococcus aureus* bacteria (Pansorbin; Calbiochem), extracted with 8 M urea/1% SDS/0.1 M dithiothreitol at 100°C and electrophoresed on 15% acrylamide/SDS gels²⁷. The acrylamide gel was impregnated with fluor (Enhance, NEN), dried down and exposed to X-ray film at -80°C . 1, pSV0; 2, prI2/SV40-46; 3, $\Delta 250$; 4, $\Delta 255$; 5, $\Delta 268$. Plasmid pSV0 is a pBR322 derivative which contains only the 416-bp SV40 origin of replication. Insulin antigen released into the culture media from transfected cells was measured by radioimmunoassay (Amersham; this assay uses human insulin as a standard and expresses concentrations in $\mu\text{U ml}^{-1}$ where pure insulin is ~ 25 units per mg); 23, 270, 206, 214 and $144 \mu\text{U ml}^{-1}$ were found in cultures 1-5, respectively.

AUG codon at the 5' end of the mRNA. As embodied in the scanning ribosome model², this hypothesis explains many characteristics of initiation by eukaryotic ribosomes (for example, the absence of polycistronic eukaryotic mRNAs). The 'first AUG' hypothesis predicts that there is no eukaryotic equivalent of a bacterial ribosome binding site, and that the 5'-proximal AUG triplet alone, with no influence from surrounding sequences, signals where polypeptide chain synthesis will initiate. We have directly tested this hypothesis by analysing mutations introduced in the 5'-noncoding region of the rat insulin II gene.

Experimental strategy

For a particular eukaryotic mRNA, if an AUG triplet is introduced into the 5'-noncoding region (upstream of the normally used initiation codon), the simple interpretation of the 'first AUG' hypothesis predicts: (1) if this new AUG codon is in the normal reading frame with no intervening termination codons, then translation will result in the expected polypeptide with an N-terminal extension; or (2) if this new AUG codon is out of the normal reading frame, then translation will not generate the expected protein. To test these predictions, we have used a rapid expression assay to evaluate rat (pre)proinsulin synthesis programmed by mutants of plasmid prI2/SV40-46³. This recombinant plasmid (see Fig. 1a) was constructed by connecting the 5'-noncoding region of the SV40 large T/small T antigen gene to the 5'-noncoding region of the rat insulin II gene. We

have previously shown that when introduced into COS cells (simian cells transformed by origin-defective SV40 mutants)⁴, the SV40 early region promoter in this construct functions to drive transcription yielding a correctly spliced hybrid SV40-insulin mRNA in which the 5'-proximal AUG triplet is the normally used rat preproinsulin initiation codon. This mRNA is translated to generate preproinsulin, which is rapidly processed to proinsulin. This system permits the rapid analysis of cloned, *in vitro* engineered mutations necessary to test the 'first AUG' hypothesis.

Construction of deletion mutants

Plasmid prI2/SV40-46 carries a unique *Hind*III site, which facilitates the engineering of AUG codons into the 5'-noncoding region of the hybrid SV40-insulin mRNA. Unfortunately, downstream from this *Hind*III site is a termination codon that is in the preproinsulin reading frame. To correct this, deletion mutants were generated using exonuclease *Bal*31 (Fig. 1b). Mutants $\Delta 255$, $\Delta 268$ and $\Delta 250$ all carry small deletions (11, 17 and 30 base pairs (bp), respectively) in the insulin 5'-noncoding region, which remove this in-frame termination codon. In COS cells, these mutants, and the parental plasmid, all programme (pre)proinsulin synthesis to similar levels (Fig. 2), demonstrating that the deleted nucleotides have no obligatory role in initiation codon selection.

Mutants $\Delta 418$, $\Delta 41$ and $\Delta 419$ carry larger deletions, which remove the upstream splice junction from the intron lying in the 5'-noncoding region. These mutants programme the synthesis of stable mRNA (Fig. 3a), in which the remaining splice junction in the 5'-noncoding region is not used (Fig. 3b). Thus, these mRNAs now carry the previously excised intronic sequences as insertions in the 5'-noncoding region, creating a new AUG codon upstream, but out of frame with the normally used initiation codon. COS cells transfected with these mutant plasmids all synthesize and secrete proinsulin (Fig. 3c), albeit slightly less efficiently than the parental plasmid. Hence, in spite of the upstream AUG, ribosomes still recognize the normally used initiation codon, clearly violating a prediction of the 'first AUG' hypothesis.

Construction of insertion mutants

To create mutants with upstream, in-frame AUG codons, fragments of pBR322 were cloned into the *Hind*III site of $\Delta 255$. Mutants $\Delta 255\text{J5}$ and $\Delta 255\text{J2}$ contain a 213-bp *Hae*III fragment, carrying six AUG codons, cloned in both orientations (Fig. 1c and 1d). Mutant $\Delta 255\text{L3}$ contains a 403-bp *Alu* fragment, carrying nine AUG codons, inserted in one orientation (Fig. 1e). The mRNAs produced by $\Delta 255\text{J5}$ and $\Delta 255\text{L3}$ will have the 5'-proximal AUG in the insulin reading frame with no intervening termination codons; all other AUG triplets are out of frame. For the mRNA produced by $\Delta 255\text{J2}$, only the sixth AUG triplet from the 5' end will be in the insulin reading frame. These mutants programme the synthesis of stable, correctly spliced mRNA (Fig. 4a) which contain the inserted pBR322 sequences intact (Fig. 4b). COS cells transfected with these mutant plasmids all synthesize proinsulin, but much less efficiently than the parental plasmid (Fig. 4c). A large insulin-immunoreactive protein (molecular weight (M_r) $\sim 21,000$) is seen in $\Delta 255\text{J5}$ transfected cells (Fig. 4c). Pulse-chase experiments (Fig. 4d) indicate that this larger protein is somewhat unstable (because of incorrect processing?) and does not chase into proinsulin.

These experiments indicate that ribosomes can recognize the normally used insulin initiation codon, in spite of it being the 7th (in $\Delta 255\text{J2}$ and $\Delta 255\text{J5}$) or 10th (in $\Delta 255\text{L3}$) AUG from the 5' end. This conclusion is supported by the ability to generate preproinsulin in a cell-free translation using mRNA from all three transfected cells (data not shown). Apparently, the first AUG is also being used on the $\Delta 255\text{J5}$ mRNA, leading to the synthesis of an $\sim 21,000$ - M_r which probably consists of preproinsulin (110 amino acids) with an N-terminal extension (87 amino acids). Thus, there are two functional initiation codons

Fig. 3 COS cells were transfected with different plasmids as described in Fig. 2. RNA was prepared³ from the 15-cm dish and examined by S_1 mapping²⁸ using end-labelled probes²⁹. *a*, Probe 1 (see Fig. 1*a*) is a 750-bp fragment uniquely 3'-end-labelled at a *Bam* site in the coding region, extending to a *Hha* site on the other side of the 499-bp intron in the coding region. If a correctly spliced mRNA anneals to the labelled anti-sense DNA strand, nuclease S_1 will digest the unhybridized intronic sequences, leaving protected a 170-nucleotide labelled fragment (designated by the arrow on the photograph of the X-ray film). 1, No RNA; 2, 10 ng of rat insulinoma poly(A⁺)RNA³; 3, 50 ng of rat insulinoma poly(A⁺)RNA; 4–8, equal amounts of RNA (1/10th of the sample) from cells transfected with pSVO, prI2/SV40-46, Δ 41, Δ 418, and Δ 419, respectively. There are $\sim 5 \times 10^7$ molecules of preproinsulin II mRNA in 10 ng of rat insulinoma poly(A⁺)RNA³. *b*, Probe 2 (see Fig. 1*a*) is a 600-bp fragment from prI2/SV40-46 uniquely 5'-end-labelled at a *Bam* site in the coding region, extending upstream to the SV40 *Eco*RI site. If a correctly spliced mRNA anneals to the labelled anti-sense DNA strand, nuclease S_1 will digest the unhybridized intronic sequences, leaving protected a 29-nucleotide labelled fragment. In the deletion mutants, if the intronic sequences are not spliced out, then S_1 will digest at the deletion end point. 1, 32 P-pBR322/*Hpa*II molecular weight numbers (chain length in nucleotides shown alongside); 2, no RNA; 3–7, equal amounts of RNA (1/10th of the sample) from cells transfected with pSVO, prI2/SV40-46, Δ 41, Δ 418 and Δ 419, respectively. *c*, Transfected cells (6 cm dish) were labelled with 35 S-cysteine and the solubilized proteins processed as described in Fig. 2. 1–5, pSVO, prI2/SV40-46, Δ 41, Δ 418 and Δ 419, respectively. Radioimmunoassay revealed 27, 288, 95, 83 and 124 μ U ml⁻¹ of insulin antigen in the spent media from cultures 1–5, respectively.

on the Δ 255J5 mRNA; the initiation codon closer to the 5'-terminus appears to be used more frequently (Fig. 4*d*) even though it probably does not function in *E. coli*⁵. No larger proteins are detected in Δ 255J2 and Δ 255L3 transfected cells, implying that these upstream in-frame AUG triplets are not used as initiation codons. It is possible that these undetected proteins might be rapidly degraded, incapable of reacting with insulin antibodies, or rapidly processed to proinsulin, but we consider this unlikely based on the properties of the 21,000-*M_r* protein programmed by Δ 255J5, the immunological characteristics of preproinsulin⁶, and the cell-free translation results which confirm the *in vivo* findings.

Implications for initiation codon selection

These data demonstrate that eukaryotic ribosomes are capable of initiating polypeptide chain synthesis at internal AUG codons, that multiple initiation sites can be used on the same mRNA, that some AUG triplets never function as initiation codons and that proximity to the 5' end modulates the efficiency of initiation codon utilization. The mere presence of an AUG triplet at the beginning of a mRNA, as predicted by the 'first AUG' hypothesis, is simply not enough information to signal translation initiation. It is likely that the structure surrounding an AUG triplet, as well as its location, are important for efficient initiation. Possibly the system described here could be used to study systematically the sequence requirements involved in initiation codon selection. Also, more experiments are necessary to see if inefficient initiation at internal AUG codons

is the result of the presence of multiple upstream AUG triplets, the increased distance between the internal initiation codon and the 5' end of the mRNA, or an altered structure around the AUG codon.

Other work lends support to the notion that the 'first AUG' hypothesis is not tenable, and that initiation codon proximity to the 5'-terminus has some role in translational efficiency. There are several eukaryotic mRNAs in which translation appears to initiate at an internal AUG triplet^{7–10} or which appear to possess two functional initiation codons^{11,12}. Mulligan and Berg¹³ have shown using a SV40 vector system that an internal AUG codon is used in bacterial xanthine-guanine phosphoribosyl transferase synthesis in mammalian cells; deletion of the upstream AUG triplets results in more efficient translation. Rosenberg and Paterson have demonstrated that the 5'-proximal coding sequence in a polycistronic prokaryotic mRNA can be translated in a eukaryotic cell-free system if this RNA carries a 5'-terminal cap structure^{14,15}; genes encoded by internal cistrons can be expressed if they are moved closer to the 5'-terminus^{15,16}. Finally, Young *et al.*¹⁷ have suggested that the different lengths of the 5'-noncoding region of mouse α -amylase mRNA may be responsible for differential amylase expression in liver and salivary gland.

If ribosomes can initiate at internal AUG codons, why are there no polycistronic mRNAs and why is the first AUG triplet used as an initiation codon on the vast majority of mRNAs? Kozak, in a modified scanning model^{7,8}, suggests that a 40S ribosomal subunit moves along the mRNA, starting from the

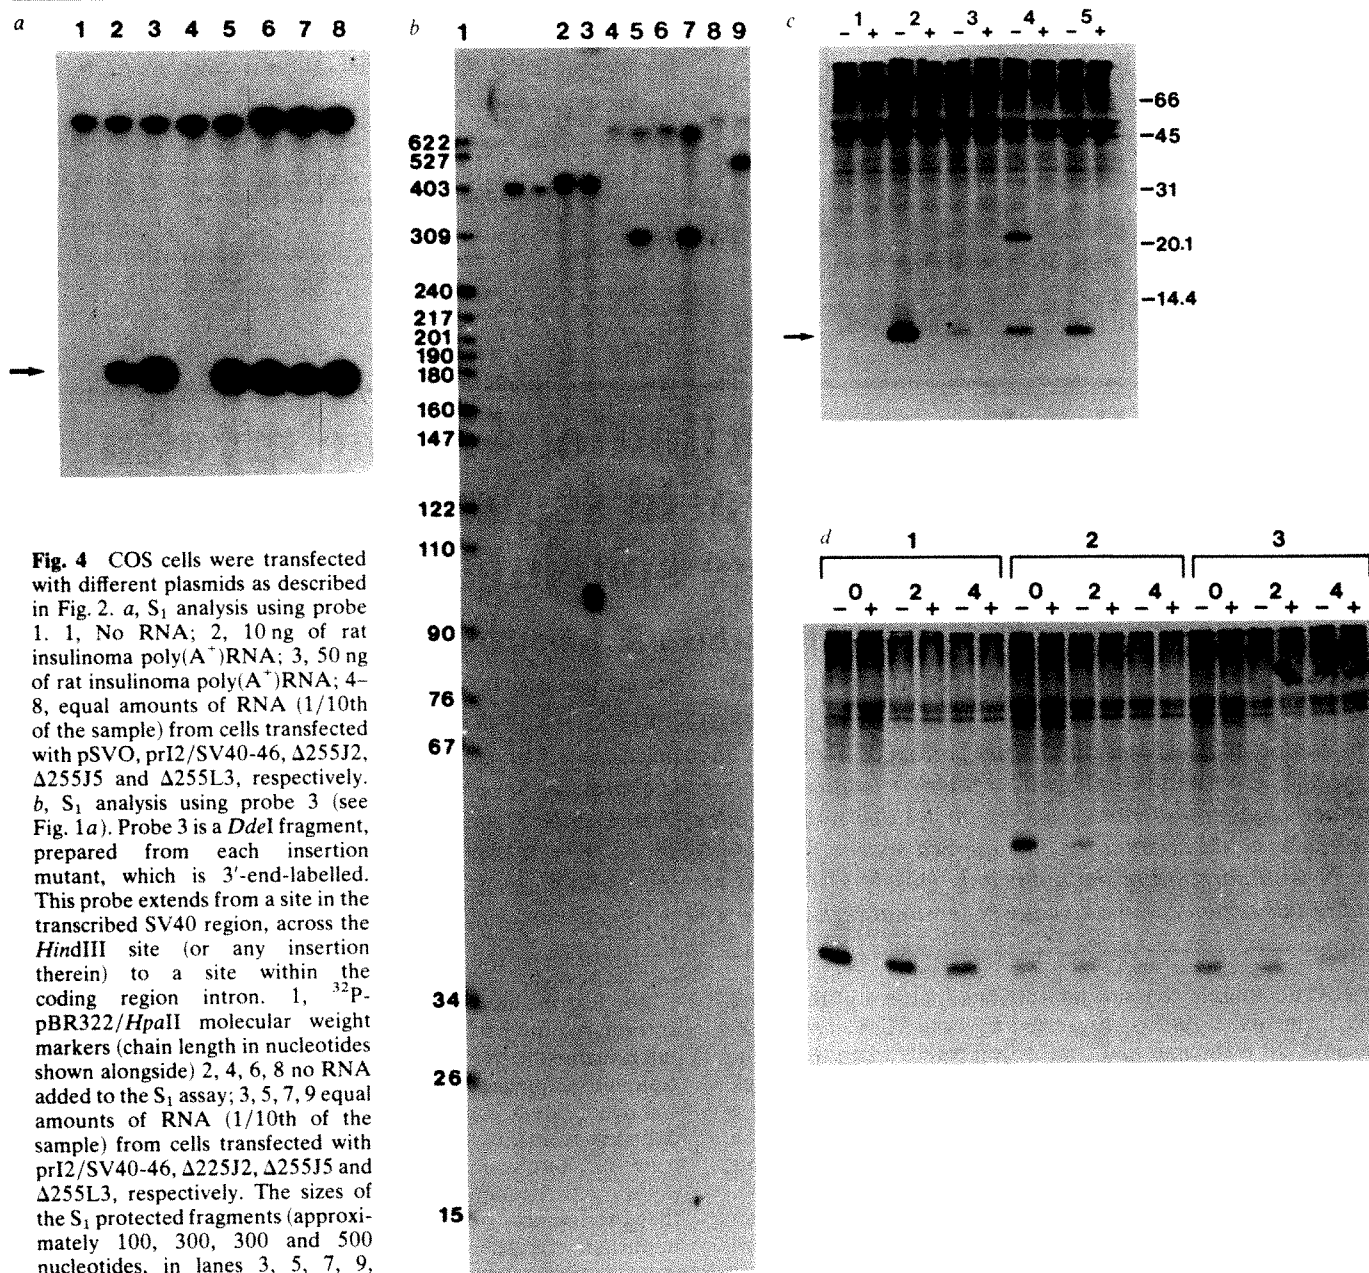

Fig. 4 COS cells were transfected with different plasmids as described in Fig. 2. *a*, S₁ analysis using probe 1. 1, No RNA; 2, 10 ng of rat insulinoma poly(A⁺)RNA; 3, 50 ng of rat insulinoma poly(A⁺)RNA; 4-8, equal amounts of RNA (1/10th of the sample) from cells transfected with pSVO, prI2/SV40-46, Δ255J2, Δ255J5 and Δ255L3, respectively. *b*, S₁ analysis using probe 3 (see Fig. 1*a*). Probe 3 is a *Dde*I fragment, prepared from each insertion mutant, which is 3'-end-labelled. This probe extends from a site in the transcribed SV40 region, across the *Hind*III site (or any insertion therein) to a site within the coding region intron. 1, ³²P-pBR322/*Hpa*II molecular weight markers (chain length in nucleotides shown alongside) 2, 4, 6, 8 no RNA added to the S₁ assay; 3, 5, 7, 9 equal amounts of RNA (1/10th of the sample) from cells transfected with prI2/SV40-46, Δ225J2, Δ255J5 and Δ255L3, respectively. The sizes of the S₁ protected fragments (approximately 100, 300, 300 and 500 nucleotides, in lanes 3, 5, 7, 9, respectively) indicate that S₁ is

attacking at the 5'-noncoding region upstream splice junction, and that the inserted sequences are preserved intact within these mRNA. Analysis using probe 2 confirms that the 5'-noncoding region intron is spliced normally in all these mRNAs. *c*, Transfected cells (6 cm dish) were labelled with ³⁵S-cysteine and the solubilized proteins processed as described in Fig. 2. 1-5, pSVO, prI2/SV40-46, Δ255J2, Δ255J5 and Δ255L3, respectively. Molecular weight markers (weight in daltons × 10⁻³) were run in a parallel lane and visualized by Coomassie blue staining. Radioimmunoassay revealed 22, 117, 29, 89 and 42 μU ml⁻¹ of insulin antigen in the spent media from cultures 1-5, respectively. *d*, Transfected cells were labelled with ³⁵S-cysteine for 15 min and collected immediately (0 h), or subjected to a 2 or 4 h chase (the radioactive media were removed and the monolayer was rinsed several times with complete media). The solubilized proteins were processed as described in Fig. 2. 1, prI2/SV40-46; 2, Δ255J5; 3, Δ255L3.

5' end, searching for AUG codons. The model predicts that flanking sequences modulate the recognition of functional AUG initiation codons by the migrating ribosomal subunit; if synthesis is not initiated at a particular AUG triplet, the scanning process continues until a functional initiation site is encountered. Functional initiation codons are found most frequently in the sequence $\hat{C}XXAUGG$. Kozak proposes that this process works most efficiently when the first AUG triplet is the functional initiation codon, thus there is a strong selective pressure against mutations that create new AUG triplets in the 5'-noncoding region. Furthermore, nature may use this process as a translational control mechanism: by placing a particular polypeptide's synthesis under the control of an internal AUG initiation codon, this polypeptide will not be produced as abundantly (the bacterial XGPRT experience¹³ fits this hypothesis). With respect to the data presented here (for example, with

Δ255J5), it seems that initiation at a particular AUG codon does not preclude initiation at a downstream AUG codon. Hence, if ribosomes do scan, initiation is curiously leaky. This problem is most notable in the Δ255L3 mRNA which possesses many potential initiation sites, as defined by the modified scanning model, upstream of the functional insulin initiation codon. In support of the modified scanning model, we find that some AUG triplets never function as initiation codons and that initiation at an AUG codon appears more efficient when this is the first AUG at the 5' end. We favour a model where eukaryotic ribosomes directly recognize certain AUG triplets which have favourable structures at the 5' end of a mRNA; proximity to the 5'-cap structure may modulate this recognition affecting the rate of polypeptide chain initiation.

We thank A. Shatkin and M. Kozak for comments on the manuscript and D. Andriola for typing.

Periodic charge distributions in the myosin rod amino acid sequence match cross-bridge spacings in muscle

Andrew D. McLachlan & Jonathan Karn

Laboratory of Molecular Biology, University Postgraduate Medical School, Hills Road, Cambridge CB2 2QH, UK

The amino acid sequence of the rod portion of nematode myosin, deduced from the sequence of the unc-54 heavy chain gene of Caenorhabditis elegans, is highly repetitive and has the characteristics of an α -helical coiled coil. The molecular surface contains alternate clusters of positive and negative charge. Interactions between charge clusters on adjacent molecules could account for the observed spacings of the myosin cross-bridges in muscle. Calculations also suggest that the N-terminal third of the rod is only loosely associated with the thick filament backbone. Bending of the rod near the end of this region could allow the N-terminal section to act as a hinged arm during muscle contraction.

STRIATED muscle contains interdigitated lattices of thick and thin filaments^{1,2}. As first suggested by both H. E. and A. F. Huxley^{3,4}, it is thought that contraction results when the actin-containing thin filaments slide past the myosin-containing thick filaments. The myosin molecule is adapted to perform both a structural task, in the assembly of the thick filament, and enzyme reactions, which generate tension. The native molecule contains two heavy chains^{5,6} each of molecular weight (MW) ~200,000. Long regions of these chains nearest the carboxyl end form an α -helical coiled coil, known as the rod, and these rods form the backbones of the thick filaments. The myosin molecule also has two globular heads^{6,7} composed of the amino ends of each heavy chain combined with the four light chains⁵. The heads act as movable cross-bridges^{1,2} between the thick and thin filaments.

Interactions between the rod segments of the myosin molecules are necessary for the assembly of thick filaments. Although the structural details vary considerably in different organisms, the general features are conserved and these are outlined in Fig. 1a. The thick filament is bipolar and contains myosin molecules assembled in an antiparallel arrangement in the central 'bare zone', which is about 1,600 Å wide^{8,9}. Throughout the rest of the filament the rods form two parallel arrays in which the heads project away from the surface, with an axial stagger of ~143 Å between heads^{10–13} and a helix repeat in vertebrates of 429 Å. These spacings give rise to the familiar X-ray diffraction pattern of muscle^{10–12}. Proteolysis of thick filaments^{5,14} and isolated myosin suggests that the backbone of the thick filament is largely formed by interactions between the C-terminal two-thirds of the myosin rod (light meromyosin or LMM), while the N-terminal third of the sequence, or subfragment-2 (S-2) region, is only loosely attached. Bending of the myosin rod in the region of the S-2–LMM junction has been postulated^{11,15} as a critical feature for the movement of the myosin cross-bridge during contraction.

We describe here how features of myosin rod sequences may account for the patterns of assembly of myosin molecules into thick filaments. We have based our analysis primarily on the complete sequence of the rod of a myosin heavy chain¹⁶ of the soil nematode, *Caenorhabditis elegans*, which we have recently deduced from DNA sequence studies of the cloned *unc-54* gene^{17–19}, but comparison of the nematode sequences with myosin rod sequences from mammals and *Drosophila* suggests that the features of the rod which we take to be structurally important are indeed maintained in all striated muscle types.

Myosin rod sequences are conserved

The complete 1,117-residue amino acid sequence of the nematode myosin rod is shown in Fig. 2. The proteolytic cleavage site at the N-terminus of the rod (the S-1–S-2 junction) is well defined and lies close to the proline residue which seems to mark the N-terminal boundary of the regular helical rod sequence (see below). Aligned with the nematode sequence are partial amino acid sequences for rabbit S-2 and LMM determined by Elzinga and his colleagues^{20,21} using protein chemistry, as well as LMM sequences of rat and *Drosophila* deduced from cDNA sequence analysis of clones by Mahdavi *et al.*²² and S. Bernstein *et al.* (personal communication). The rod sequences are homologous along their entire lengths and show high levels of matching amino acids. For example, there are 42.5% matching amino acids between the nematode and rabbit sequences from the beginning of the rod to residue 463, and 48.1% matching amino acids between nematode and rat from residues 673 to the end of the rod sequence at residue 1,100. The two mammalian sequences are even more highly conserved and show 75.9% amino acid homology from residues 787 to 1,098. Most of the sequence alterations are conservative, particularly at positions in the molecule where charged or hydrophobic residues are preferred, so that the chemical characteristics of the sequences are preserved.

Fig. 1 *a*, Schematic drawing of the bipolar arrangement of myosin molecules in the thick filament. The filaments extend in both directions from the mid-line (M) and the globular heads form a regular array of cross-bridges with an axial separation of ~ 143 Å in vertebrate striated muscle and a helix repeat of 430 Å. The central bare zone, free of cross-bridges, is $\sim 1,600$ Å wide. Each molecule contains two chains (one only shown here) composed of the head, S-1, a helical rod-like arm, S-2, and a rod-like core segment, LMM. The width is not to scale. A typical complete vertebrate thick filament is $\sim 15,700$ Å long, with 49 levels of cross-bridges on each end and three cross-bridges emerging at each level^{2,8}. *b*, Parallel array of staggered myosin rods, drawn to show the relationship between the 143 Å (or 98-residue) and 430 Å (294 or 295 residues) displacements and the 28-residue zones in the amino acid sequence, as shown in Fig. 2. In rods numbered 0-2, open circles represent the zones in short S-2, ending within zone 12, and closed circles are zones in long S-2 or LMM. Vertical bars mark skip residues and the open square beyond zone 40 is the non-helical tailpiece. Rods 3-12 emphasize the half-staggered arrangement of skip residues. The diagram is a two-dimensional view of the stagger and should not be taken literally. The numbers at the right of the ends of the rods show the staggers in amino acid residues 0, 98, 294... A cross section through one such staggered array contains approximately 12 rods if S-2 is bound to the backbone or 8 rods when S-2 is bent away in zone 12. Vertebrate striated muscle probably has the equivalent of three such arrays in each cross-section.

28-Residue repeat units and helical structure of the myosin rod

The myosin rod sequence is highly repetitive and shows features typical of an α -helical coiled-coil protein. Between residues 2 and 1,088 the predicted α -helix probability profile²³ is high almost everywhere, with levels of 70-90% except for 15 local weak spots with a level below 50%. This whole region contains no proline. Beyond residue 1,088 the helix seems to end, leading into a tailpiece, Pro 1,095-Phe 1,117, with an apparently irregular secondary structure.

Many α -helical coiled-coil proteins²⁴⁻²⁶, especially tropomyosin^{27,28}, fibrinogen^{29,30} and α -keratin³¹, have a characteristic regular 7-residue pattern *a, b, c, d, e, f, g*, in which hydrophobic residues are concentrated at alternate intervals of three and four residues along the lengths of the chain at positions *a* and *d* (refs 24, 32). The residues at positions *a* and *d* form a closely packed hydrophobic interface or 'core' of knobs and holes between the two strands of the coiled coil³³. Fragments of the rabbit skeletal myosin rod sequence have already been found^{21,34} which show a marked 7-residue hydrophobic repeat, though less regular than that in tropomyosin²⁸. The histograms in Fig. 3 show how the complete nematode rod sequence has hydrophobic residues strongly concentrated in the core positions *a* and *d*. The helix surface is highly charged, with acidic and basic residues clustered mainly in the outer positions *b, c* and *f*.

Several fibrous proteins^{35,36} have longer repeated structural units which are important in the assembly and function of these molecules. The myosin rod shows strong evidence for a 28-

residue unit with a repetitive sequence as suggested originally by Parry³⁷ in his analyses of the rabbit myosin sequence determined by Elzinga *et al.*^{20,21,34}. Comparison of the sequence with itself shows that the entire helical sequence of the coil can be mapped out as a cyclical pattern of 28 amino acids. The statistical analysis of the pattern and its significance will be given elsewhere. We stress here two features which appear relevant to the rod structure. First, the repeat pattern is interrupted at four positions by the insertion of one extra residue which we call a 'skip residue'. As will be discussed below, these residues probably modulate the pitch of the coiled coil, a possibility previously proposed by Elzinga and Trus³⁸. Second, the distribution of the charges on the helix surface suggests that the rods are held in the thick filament structure by electrostatic forces between rods which lie side by side.

The positions of the skip residues are narrowly defined to within one or two turns of α -helix, and we have assigned them to residues 351, 548, 745 and 970, which are separated by regular intervening regions with lengths which are exact multiples of 28—196, 196 and 224, respectively. When aligned in this way, the coil region divides into 41 zones, 38 of which show a complete 28-residue cycle composed of four 7-residue sections with the characteristic coiled-coil pattern, beginning at position *d*. The 28 positions in a zone can thus be labelled 1*d*, 1*e*, ... 1*c*, 2*d*, 2*e*, ... 4*b*, 4*c*. With this convention the skip residues all occur at the end of a zone after position *c*, and the next zone begins at position *d*. The arrangement of repeat units and skip residues suggests that the whole sequence has evolved from a primitive 28-residue segment by a series of gene multiplication steps, perhaps involving a longer 197-residue structural unit in the later stages.

Each zone has a characteristic pattern of hydrophobic residues and a remarkable distribution of charges. The histograms in Fig. 3 show these patterns, which are drawn more realistically on a helical net diagram in Fig. 4. A typical 28-residue zone divides into six alternating bands of positive and negative charge which are spaced so that the strongest peak of positive charge (position 1*b*) is exactly 14 residues (or one half-zone) away from the strongest peak of negative charge (position 3*b*). A Fourier analysis of the charge distribution shows very intense peaks at periods of 28 and 28/3 residues in both the acidic and basic amino acids. Parry detected some of these peaks in earlier sequence fragments³⁷.

The hydrophobic residues are not uniformly distributed throughout the 28-residue zones and some positions such as 1*a* and 4*d* are particularly weak, because of the displacement of hydrophobic residues by charged amino acids. Lysine and arginine often appear in the *a* core positions (31 examples). The negatively charged side chains of aspartic and glutamic acid are, however, totally excluded from position *a* and are rare in position *d* (15 examples) except near the maxima of the negative charge pattern.

Although individual zones differ, the character of a typical 28-amino acid zone may be summed up in a 'consensus' sequence derived by taking the most common residue at each position:

<i>d</i>	<i>e</i>	<i>f</i>	<i>g</i>	<i>a</i>	<i>b</i>	<i>c</i>	<i>d</i>	<i>e</i>	<i>f</i>	<i>g</i>	<i>a</i>	<i>b</i>	<i>c</i>
L-E-K-Q-K-K-K-L-E-Q-E-L-E-E	(1-14)												
L-Q-E-Q-L-D-E-E-E-R-A-L-A-K	(15-28)												

Skip residues and the coiled-coil pitch

The skip residues appear at homologous positions in each of the species studied so far, and break the 7-residue pattern of the coiled-coil sequence. We built space-filling models of the skip regions and several comparable 56-residue lengths of the regular coil to test whether the extra residue produced a complete break in the coiled coil or merely a minor deformation. Reasonable limits for the pitch of the regular supercoil range

Fig. 2 28-Residue repeats and skip points in the coil region sequence. Complete sequence from nematode (NEM), with aligned fragments from rabbit (RBT), rat and *Drosophila* (DRO) myosins. The sequence divides into 41 zones. The first zone is short, with only 14 residues, and the helical region ends near residue 1,094 in zone 40. Above the 28 columns letters *d*, *e*, *f*, *g*, *a*, *b*, *c* indicate positions in the 7-residue coiled-coil repeat; Asterisks mark positions *a*, *d* on the inner face of the coil which often contain hydrophobic amino acids. Skip residues are shown on the right-hand margin at positions 351, 548, 745 and 970. Special features are: S2-A, junction of short S-2 with long LMM; S2-B, junction of long S-2 with short LMM; the non-helical tailpiece, residues 1,095-1,117.

from 92 amino acids (137 Å) in tropomyosin^{28,39} through 90–120 in paramyosin^{40,41} up to 126 for an ideal α -helix with 3.6 residues per turn. In our models we assumed a twist of $\sim 90^\circ$ over each regular 28-residue zone, corresponding to a pitch of 112 residues.

All the models of regular regions confirm that the hydrophobic core of the supercoil is well packed together when the chains are in register. In each skip region the models suggest that the supercoil can accommodate the extra residues by yielding to local distortions without any severe alteration of the structure. The seam of hydrophobic residues shifts across the helix surface over a stretch of 14–21 residues and resumes its regular zig-zag pattern at the far side of the region. Figure 4 shows an example of this near residue 351 (the models will be described in more detail elsewhere). The main overall effect is to flatten out the twist of the supercoil and make the helices run parallel to one another for a few turns. The local pitch distortions produced by the skip residues could have important effects on the way myosin molecules pack in the cross-sections of the thick filaments.

Electrostatic interactions between the rods

The regular bands of charge on the rod suggest that strong attractions and repulsions will arise when two molecules are placed side by side. We have analysed these interactions for parallel chains using a linear model⁴², as if the charge distributions were averaged round the circumference of the helix surface. A more realistic analysis based on a three-dimensional model would certainly be preferable, but at present this is not possible, as the pitch of the coiled coil is unknown. The zone structure of the myosin rod sequence suggests³⁷ that there should be strong repulsions when the stagger is zero or a multiple of 28 residues, and strong attractions when it is an odd multiple of 14 residues. Our calculations confirm this and show that particularly strong attractions are expected for staggers of 98 or 294 residues.

Fig. 3 Histograms of amino acid distributions in the 28-residue zones. The data are for the 38 complete zones in the nematode only. The 28 bars correspond to the 28 columns in Fig. 2, with the skip residues omitted. The heights of the bars were obtained by counting the amino acids in the columns. The upper histogram shows the net charge (positive minus negative). Triangles show the positions of the six main bands of charge in the average zone. Asterisks mark the core positions in the hydrophobic residue pattern. The cross-section of the coiled coil (above) shows how the positions *a-g* appear when viewed from the amino end of the parallel helices:

Figure 5 shows how the net electrostatic interaction between two parallel rod sequences depends on the axial stagger. A pair of molecules was treated as two linear arrays of charged and uncharged amino acids shifted successively by 0, 1, 2, ... n residues. Two charges were considered to interact if they lay nearly opposite one another, within a range of 0, ± 1 , ± 2 residues. In these calculations only the acidic and basic amino acids were considered and the coil was taken to have a length of 1,094 residues, ignoring the non-helical tailpiece, at residues 1,095–1,117. The energy oscillates strongly with stagger, showing a 28-residue period, and has peaks close to the odd multiples of 14. The amplitude decreases as the molecular overlap is reduced, but not uniformly, and several peaks stand out. The most prominent are at odd multiples of staggers of 98—for example, 98, 294 (98×3) and 490 (98×5). A stagger of 98 residues or $3\frac{1}{2}$ complete zones would correspond to a distance of 145.5 Å, assuming a helical rise of 1.485 Å per residue⁴³ in the α -helical coiled coil. This distance is close to the cross-bridge translation of 143–146 Å observed in muscle. A small correction is required for an average of one skip residue every 196 residues, so that the theoretical step length would be 98.5 residues or 146.3 Å. A further unknown correction is needed if the rods bend, or if they run at a small angle to the thick filament axis. The interactions seen at staggers that are odd multiples of 98 allow for several kinds of nearest neighbour in the close-packing of myosin rods in three dimensions. Thus, the stagger of 294 residues accounts for the interactions between ideal straight molecules translated by 436.5 Å or between real molecules at the axial helical repeat distance of 430 Å seen in muscle. Similarly, the interactions at a 490-residue stagger reflect potential interactions between molecules further apart in the helix.

This overlap calculation does not show which portions of the rod interact most strongly, nor whether attractions and repulsions are equally important. A more detailed picture was built up by calculating local interactions between shorter segments of staggered rods with a certain span length. Trials showed that the clearest results were obtained when attractions and repulsions had equal weights and when interactions were averaged over long spans of 99–589 residues.

Significant interactions appear at most staggers which are half-integer multiples of 28, especially in the first half of the molecule, but the strongest and most persistent interaction is at a stagger of 98. In Fig. 6 the interaction density summed over a span of 99 residues is plotted along the length of the rod for staggers of 294, 100, 98 and 96 residues. The favourable interactions for a stagger of 98 stand out clearly. The strong peak centred on residue 320 corresponds to the attraction between residues 271–369 of one rod and 173–271 of its neighbour, displaced 98 residues towards the carboxyl end. The pairing persists strongly down to the shoulder near residue 880. The interactions at a stagger of 294 residues are generally weaker and they appear mainly in the second half of the molecule. The high plateau from residues 740–1,008 in Fig. 6 corresponds to a strong averaged interaction in the LMM fragment between residues 691–1,057 and 593–959, with a stagger of 294 residues which corresponds to the helix repeat distance in vertebrate muscle.

Search for a hinge between S-2 and LMM

It has been suggested that myosin contains flexible sections or hinges. A hinge in the rod between S-2 and LMM could allow the cross-bridge to move in or out from the thick filament backbone^{10,15}. Electron microscope observations of sharp bends in isolated myosin rods^{7,44} support this notion. Also, proteolysis of myosins from a wide variety of species^{5,6,14} shows that the rod tends to cleave at narrowly localized points, which may reflect the presence of hinges. In rabbit skeletal muscle either a 37,000-MW fragment (short S-2) or a 59,000-MW one (long S-2) can be cleaved from the amino end of the rod. Analysis of the rabbit fragments^{21,38,45,46} suggests that the C-terminus of short S-2 is homologous to a region in the nematode between

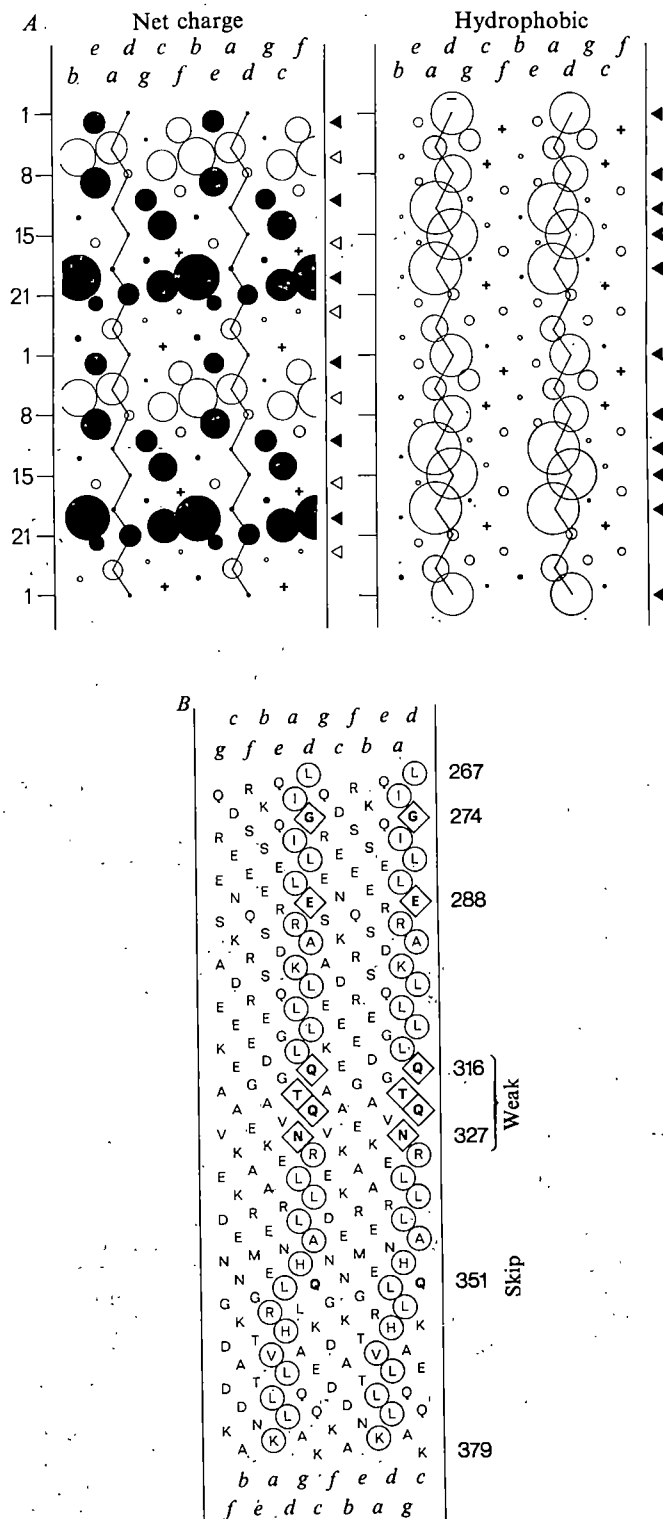

Fig. 4 A, charge distribution and hydrophobic residues for the averaged 28-residue zone plotted on the supercoil surface of two paired α -helices. A section of coil 56 residues long has been projected onto a cylinder and unrolled so that each section of sequence appears twice side-by-side, first on one helix and then on the other. The sequence reads across from right to left with a slight downward slant and is drawn with a pitch of $3\frac{1}{2}$ residues per turn. Inner positions a, d are connected by a zig-zag line. Circles have radii proportional to the numbers in Fig. 3, with white and black to represent positive and negative charges. A (+) sign marks points of zero net charge. Triangles at the side mark six bands of charge in the typical zone. Hydrophobic residues are plotted in a similar way with triangles to mark the major sites and (+) signs to mark forbidden positions. B, helical net of part of the coiled-coil sequence to illustrate the interrupted pattern of hydrophobic residues in the core. Hydrophobic or basic amino acid side chains are ringed, while diamonds enclose acidic, polar or glycine side chains, which are likely to weaken the core. At skip residue Gln 351 the pattern shifts across the helix surface. Residues 316–327 may form an unusually weak part of the coil and they lie near the short S-2–LMM junction.

Fig. 5 Charge interactions between parallel rods 1,094 residues long. The stagger, s , is plotted horizontally and the net number of interactions (attractions minus repulsions) vertically. Amino acids are counted within an axial range of ± 2 residues, taking each rod as a single chain, because only one side at a time can interact with its neighbour. Note the peaks at staggers which are odd multiples of 98.

lysines 312 and 328, which would give a molecular weight of between 36,173 and 37,783. The remainder of the rod, possibly the longest LMM fragment, would then have a MW of 91,386 or 89,776. Lu and Wong⁴⁵ have also demonstrated that fragments of rabbit myosin homologous to residues 326–386 are present in long but not short S-2. The long S-2–LMM junction⁴⁶ is near Lys 517. Cleavage at this point would lead to a 59,313-MW fragment and a corresponding form of LMM with MW 68,246.

There is no part of the nematode rod or the vertebrate sequence fragments which seems at all likely to form a specific non-helical molecular hinge distinct from the coiled coil. The short S-2 region and LMM are predicted to be α -helical to the same extent and the 28-residue repeat pattern is strong in both regions. The total net charge differs little. The skip regions do not seem to correspond to the hinges defined by proteolysis. The first skip residue, at position 351, and the second at 548 lie well to the C-terminal sides of the likely cleavage sites for short and long S-2. There is no evidence for specific cleavages near the third and fourth skip residues.

We searched the nematode sequence for potential weak spots where several consecutive missing hydrophobic residues in the core might disturb the coiled-coil structure. The sequences in Fig. 2 and the histograms in Fig. 3 suggest that Ala can substitute satisfactorily for Leu, Val or Ile in the core positions a and d , while the hydrophobic basic groups Arg and Lys are tolerated more readily than Asp and Glu. Therefore, we looked for regions with polar, negatively charged, or glycine residues in positions a and d . With this rule the weakest sections of the coil seem to be positions 316–327, with four consecutive defects, and 176–183 and 823–830 with three each. The section 316–327, which is one of the most pronounced of these potential weak points, lies close to the point of division between the short and long S-2 fragments in rabbit^{45,46}. We have also obtained (J. K. and L. Barnett, unpublished) the sequences of two other nematode heavy chains in the region 316–327. In one gene the sequence is identical to *unc-54*, but the second shows an apparently stronger structure in which Leu replaces Thr 320 and strengthens the core.

The freedom of movement of the S-2 region must also depend on its interactions with the rest of the filament. Our analysis of the electrostatic interactions between parallel rods (Fig. 6) suggests that the N-terminal part of the short S-2 region has a weakened attraction, or even repulsion, for other molecules aligned with staggers close to 98 residues, whereas the middle section, residues 173–271, has a strong attraction for residues 271–369 of an adjoining molecule. At certain staggers the tip of S-2 can be attracted to other sections of the myosin rod. A particularly strong interaction appears when the stagger is 95 or 96.

Our analysis suggests that the S-2 region is held against the rest of the thick filament by a comparatively weak 'electrostatic spring' which allows the tip of the rod to bend outwards under stress. Residues 316–327 may be a 'soft spot' in the coiled coil

where the α -helix can bend or even unravel and extend locally⁴⁷ to accommodate the movement.

Structure of thick filaments

The high density of charged groups on the outer surface of the myosin rod and the lack of hydrophobic groups on the surface suggest that ionic interactions are by far the most important forces involved in the assembly of thick filaments. We have seen that the rod sequence is made up of structurally similar repeat units which are 28 residues (or 41.6 Å) long, which have a characteristic charge distribution and attract one another strongly when they are half-staggered by half-integer multiples of their length. Our one-dimensional model calculations suggest that direct interactions between complementary charges on parallel rods staggered by 98 or 294 residues may account for the 143 and 430 Å axial spacings found in muscle. Our result

Fig. 6 The distribution of charge interactions along the length of a pair of parallel rods. The upper rod is fixed and the lower rod has been shifted s residues to the right. The curves are drawn for shifts of 96, 98, 100 and 294 residues and the positions of the rods shown here correspond to the 98-residue shift. The height of the graph under residue n of the upper rod is equal to the sum (attractions–repulsions) of a 99-residue section centred on residue n and the adjacent 99-residue section of the lower rod centred on residue $(n-s)$. When residue n nears the end of the sequence the 99-residue active zone becomes shortened and the interactions gradually decrease at each end. Thus, the top curve for a shift of 294 residues reaches its peaks between residues 343 and 1,045. The interactions are scored in the same way as in Fig. 5. Inside each 99-residue section the charge pairs are counted within an axial range of ± 2 residues. The relationship between the zone and the scoring is shown schematically in the upper diagram (not to scale). The S2–LMM junction has been placed at residue 322 and refers to the upper rod.

that the 294-residue stagger leads to strong attractions in the LMM segment agrees with some observations on LMM paracrystals^{48,49}. The 430 Å stagger often coexists in a phase equilibrium with the 143 Å stagger. The 143 and 430 Å spacings associated with the myosin molecule are both close to half-integral multiples of 286 Å and suggest³⁷ that the long spacings in muscle are produced by electrostatic interactions between larger-scale structural units ~196 or 197 residues long, which form a variety of half-staggered fibrous arrays. The two 197-residue sections of myosin rod, 351–547 and 548–744, bounded by the first three skip residues, may therefore be discrete structural units in the assembly of the thick filament. If this type of structural scheme is correct, it would suggest that paramyosin⁵⁰, which assembles with a long spacing of 725 Å ($2\frac{1}{2}$ times 290 Å), also contains 28-residue zones and skip residues, and that the shorter 290 Å network spacing in paramyosin results from a combination of opposed half-integer spacings of 725 and 435 Å.

We have not yet extended our calculations to analyse the three-dimensional packing of myosin rods in the thick filaments. All such models² depend crucially on the pitch of the supercoil, and in myosin the presence of skip residues which probably modulate the pitch is an added complication. Two funda-

mentally different types of attraction are possible; direct salt bridges⁵¹ or indirect ion-bridged couplings between clusters of like charges⁵². Packing schemes which only allow direct salt bridges are quite restricted. A cross-section through the filament at each level must contain a lattice of alternating positive and negative charges with nearest neighbours formed into even-membered sub-assemblies of 2, 4, 6, ... two-stranded myosin rods. The simplest regular assemblies of this type have square or hexagonal cross-section lattices. The presence of 28-residue zones throughout the sequence suggests that the packing may originally have evolved from a regular crystalline lattice in which amino acids separated by 28 residues occupied equivalent sites.

Finally, we note that numerous mutants of the *unc-54* gene have been isolated which show defects in the thick filament assembly. Analysis of the sequence alterations in these strains should provide an experimental framework for testing the ideas presented here.

We thank M. Elzinga, S. Tong, R. C. Lu, V. Moldavi, B. Nadal-Ginard and S. Bernstein for allowing us to use their unpublished sequence data; M. Stewart, R. W. Craig, A. G. Weeds, H. E. Huxley, P. Goelet and L. Barnett for helpful discussions; and S. Brenner for his enthusiastic support.

The effects of α chain mutations *cis* and *trans* to the $\beta 6$ mutation on the polymerization of sickle cell haemoglobin

Ruth E. Benesch, Suzanna Kwong & Reinhold Benesch

Department of Biochemistry, Columbia University, College of Physicians and Surgeons, New York, New York 10032, USA

*The solubility of polymers formed by haemoglobins with one β^S chain and one mutant α chain, either *cis* or *trans* to each other, has revealed three distinct regions on the surface of the tetramer which participate in intermolecular bonding within the haemoglobin S fibre.*

It has become increasingly clear that the polymer formed from concentrated solutions of deoxygenated sickle cell haemoglobin (HbS) is a multi-stranded helix, the basic unit of which is the double-stranded structure described for HbS crystals by Wishner *et al.*¹. This is supported by the spontaneous transfor-

mation of fibres into crystals that show the same diffraction pattern as those studied by Wishner *et al.*, which has been demonstrated for fibres stored for very long periods of time², and also for fibres stirred to accelerate their transformation to crystals^{3–5}—in which case a considerable polymorphism of the

intermediate structures formed during crystallization can be observed.

The link between the HbS fibre structure and that of the Wishner double strand is also supported by the demonstration that many of the mutations that interfere with HbS gelation are located at residues that form contacts between the haemoglobin molecules in the Wishner crystal⁶⁻⁹. The significance of the double strands as the basic unit from which the fibres are constructed is also illustrated by the observation that specific pairs of strands are missing from the fibre structure in certain conditions. This was found in minor forms of HbS fibres¹⁰ as well as in the principal form of the fibres of the double mutant haemoglobin $\alpha_2^{\text{Sealy}} \beta_2^{\text{S}}$ (ref. 11).

In HbS crystals the molecules are arranged in paired strands with tetramers in adjacent strands staggered by half a molecular diameter¹. The lateral contact between members of a pair involves the HbS mutation in only one of the β chains of a tetramer—a hydrophobic bond between valine 6 of the β_2 chain of a tetramer in one strand with residues on the haem pocket of the β_1 chain of a molecule in the adjacent strand. It follows that in the crystal (and therefore also in the fibre) the two β chains, and hence also the two α chains, are not equivalent and that residues on the surface of the α_1 and the α_2 chain will be involved in different groups of intermolecular contacts. The different role of the two β chains in the polymerization was first demonstrated in solution by the effect of HbA on the polymerization of HbC-Harlem¹², and later by the finding that tetramers containing only one β^{S} chain can form gels^{13,14}.

As the structure of the fibres of deoxy HbS has not been solved unequivocally, several models have been proposed for

Fig. 1 The effect of the cross-link on oxygenation curves. These were determined spectrophotometrically as described elsewhere^{29,30}. ●, HbS; ▲, cross-linked HbS; ■, cross-linked HbAS. 0.05 M bis Tris buffer, pH 7.3, 0.1 M chloride, 20 °C.

fibres composed of four¹⁵, seven^{10,16,17} or eight¹⁸ 'Wishner double strands'. Of these, the eight-stranded one is the most unlikely, having been proposed before the non-hollow structure of the fibres was recognized. The 16-stranded model was proposed on the basis of the fibre to crystal transformation^{3,18}, but only the 14-stranded structure results from direct image reconstruction of the fibre itself^{10,16,17}.

In such a multi-stranded helix at least three classes of intermolecular contacts can be distinguished: (1) The axial contact between molecules within a single strand. These contacts will be similar in all strands throughout the fibre. (2) The lateral contact between members of a double strand, described above. Again, this contact will exist throughout the structure, and β_1 6 valines do not participate. (3) A much more diverse group of contacts are those that hold the double strands together to form the multi-stranded helix. They are not only much less well characterized, but are necessarily of several different kinds, particularly in the case of the 14-stranded structure. These contacts must be different from the inter-pair ones in the crystal, and they are, of course, especially relevant for the stability of the fibre structure.

Double mutants, containing the β^{S} mutation and an additional one on the α chains, have previously been used to define regions on the α chain that participate in the intermolecular contacts⁶⁻⁸. As pointed out by Nagel *et al.*⁹, the conclusions that can be reached by this approach are limited from a stereochemical point of view, as both α chains and both β chains are substituted in these tetramers.

As only one of the β 6 valines participates in the bonding between the two partners of a double strand, the effect of an α chain mutation will depend on its position relative to the contact-forming β^{S} chain (β_2). With this in mind we have prepared tetramers containing only one β^{S} chain (the other one being β^{A}) so that an α chain mutation could be placed either on the same dimer as the β^{S} mutation (*cis*) or on the opposite one (*trans*). Because such haemoglobin tetramers, consisting of two different $\alpha\beta$ dimers, disproportionate to homogeneous ones during aerobic chromatography, they were isolated by using a specific covalent cross-link between the β chains^{19,20}.

The results presented here show that these molecules could be used to test some of the predictions which emerge from the proposed models of the sickle fibre.

Preparation of mixed tetramers

The general approach was to mix equal amounts of the two haemoglobins in aerobic conditions to allow for $\alpha\beta$ dimer exchange which results in a mixture containing 50% of the hybrid and 25% of each of the parent haemoglobins. The mixture was deoxygenated to freeze the equilibrium, and an intra-dimeric cross-link was introduced by reaction with 1.4 mols of 2-nor-2 formylpyridoxal 5' phosphate per mol of haemoglobin, followed by reduction with NaBH_4 as described previously^{19,20}.

HbA was obtained from normal human blood as described previously²³. HbS ($\alpha_2\beta_2^{\text{S}}$), Hb^{Sealy} ($\alpha_2^{\text{Sealy}}\beta_2^{\text{S}}$) and Hb¹ ($\alpha_2^{\text{16Lys}}\beta_2^{\text{S}}$) were isolated from the blood of heterozygous donors using the chromatographic system of Abraham *et al.*²⁴ on a preparative scale²⁵. Polymerization was induced by reduction with two equivalents of deoxygenated dithionite per haem, the gels were centrifuged and the haemoglobin concentration was determined in the supernatant as described elsewhere²⁶. For many of the experiments the volume of haemoglobin solution necessary was decreased to 80–100 μ l by using centrifuge tubes 45 mm in length made from Pyrex capillary tubing (i.d. 2 mm, o.d. 5 mm). The supernatant concentration (c_{sat}) is independent of the initial concentration²⁵. Because these concentrated solutions are highly non-ideal, c_{sat} must be multiplied by the activity coefficient (γ)²⁷ to obtain a thermodynamic measure of the polymerizing tendency (a_{sat}).

Table 2 Gel solubility of tetramers with *cis* and *trans* $\alpha 16$ mutations

<i>trans</i> $\left[\begin{smallmatrix} \beta^S \alpha^A \\ \beta^A \alpha^I \end{smallmatrix} \right]$	19.7 ± 0.2 (3)	5.5	108	1.0

Following the NaBH_4 reduction, all haemoglobins were converted to the metcyanide form by oxidation at pH 7.0 and room temperature with 1.2 equivalents of $\text{K}_3\text{Fe}(\text{CN})_6$ per haem in the presence of 2.0 equivalents of KCN. Ferri cyanide and ferrocyanide were removed by passage through Sephadex G-25 in 0.1 M phosphate buffer pH 7.3 containing 10^{-2} M KCN. The three cross-linked species (the hybrid and the two parent haemoglobins) were then separated from uncross-linked haemoglobins by passage of the mixture through a 4×52 cm Sephadex G-100 column in 1 M MgCl_2 , 0.1% Tris pH 7.0, 10^{-2} M KCN at 18 ml h^{-1} (ref. 28). The isolation of the desired cross-linked haemoglobins was again accomplished by the Abraham method²⁴ using sectional columns²⁵. This method resulted in excellent separations of all the components of the mixtures except in the case of the *trans* isomer of the Hb^{Sealy} :HbS hybrid. Since HbS, Hb^{Sealy} and the hybrid all have the same charge in neutral solution, a lower pH to protonate the $\alpha 47$ histidine of Hb^{Sealy} was used to resolve this mixture. This was done by chromatography on CM-Sephadex in 0.05 M phosphate buffer pH 6.0 with a gradient of NaCl from 0 to 0.1 M. After elution all haemoglobin solutions were dialyzed to equilibrium against 0.1 M phosphate buffer pH 7.3 containing 0.01 M KCN. They were then concentrated as described previously²⁵.

(1) *Trans* tetramers, with the α and β chain mutations on different $\alpha\beta$ dimers. These are made by mixing HbS and the α mutant haemoglobin, thus:

(2) *Cis* tetramers, with the α and β chain mutations on the same $\alpha\beta$ dimer. The starting material for this kind of tetramer was the double mutant, $\alpha^X \beta^S$, prepared by previously described methods⁶⁻⁸. The *cis* tetramer is formed by subunit exchange of this double mutant with HbA, thus:

The structure of these mixed tetramers is unequivocally determined by their method of preparation, as the dissociation of haemoglobin in neutral solution does not proceed beyond the $\alpha\beta$ dimer stage.

The pyridoxal phosphate dialdehyde used throughout this investigation for stabilizing the mixed tetramers provides a single covalent bridge between the N-terminal amino group of one β chain and lysine 82 of the other β chain, across the polyphosphate binding site²¹. This cross-link greatly lowers the

O_2 affinity (Fig. 1) to values similar to those found in the presence of excess inositol hexaphosphate. Furthermore, the cross-link does not appear to alter the structure of the fibres, as cross-linked HbS fibres are typical of those of normal HbS in the presence of organophosphates (Fig. 2).

Polymerization studies

The effect of the two mutations in the α chain ($\alpha 16$ and $\alpha 47$) on the gel solubility of tetramers that also carry the β^S mutation is compared in Table 1. Three types of tetramers were initially studied: (1) Uncross-linked tetramers in which both α chains and both β chains are substituted. (2) The same tetramers cross-linked between the β chains. (3) Cross-linked tetramers in which both α chains are mutant ones, but only one β chain is β^S .

It is clear that in all cases the solubilizing effect of the $\alpha 16$ substitution far exceeds that at $\alpha 47$. Both these mutations were previously reported to increase the solubility in concentrated phosphate, but with their relative effectiveness reversed. This was probably due to the influence of the high ionic strength used in this assay on the electrostatic interactions responsible for these contacts⁶. A comparison of the results for (2) and (3) shows that the tetramers containing only one β^S chain behave similarly to the ones with two β^S chains except for a higher solubility. The somewhat lowered gel solubility of cross-linked compared with uncross-linked HbS (Table 1) also shows that this modification does not interfere with polymerization but actually favours it, probably because it fits so well into the deoxyconformation of the central cavity²¹.

The results in Table 2 show the dramatic difference in the effect of the $\alpha 16$ mutation in the *cis* compared with the *trans* configuration. The tetramer in which both mutations are present on the same $\alpha\beta$ dimer (*cis*) is almost 10 times as soluble as the *trans* tetramer, which has the same solubility as the one in which both α chains are normal (Table 2). As substitution of glutamate for lysine at position 16 in the *trans* α chain has no effect on polymerization, the mutation in the *cis* position must be responsible for the whole solubilizing effect observed when both α chains are mutant ones.

The corresponding data for the $\alpha 47$ mutation are shown in Table 3. In this case substitution of mutant for normal α chains in both positions affects polymerization, but in opposite directions. While the mutation in the *cis* α chain causes an increase in solubility, the same substitution in the *trans* α chain actually decreases it (Table 3). The extent to which these two opposing effects neutralize each other evidently depends on the kind of tetramer into which the two α chain mutations are introduced. In uncross-linked HbS the solubilizing effect prevails (Table 1a) whereas in the cross-linked ones the two effects largely cancel each other (Table 1b, c).

Discussion

The striking difference in the solubility of the *cis* and *trans* isomers of both mutations testifies to the different role that each of the α chains has in the formation of the HbS fibre.

In the case of the $\alpha 16$ mutation, substitution of the normal

Experimental details were as for Table 2.

lysine by a glutamate in the α_2 chain causes a very large increase in gel solubility, whereas the same substitution in the α_1 chain has no effect at all. According to Wishner *et al.*¹ lysine α_2 16 is situated in the axial contact between the molecules along a single strand, and the normal attraction between this lysine and glutamate β 22 in the next molecule would then be replaced by a repulsion in the mutant. Lysine α_1 16, on the other hand, is not involved in any of the contacts of the Wishner-Love structure. Our results with the α 16 mutation therefore strongly support the Wishner-Love double strand as a basic unit of the HbS fibre.

The significance of the α 16 locus for the polymerization of HbS raises the possibility of using it as a receptor site for antisickling modifications. In this connection it is of interest that Acharya and Manning found that lysine α 16 was the most reactive residue in the α chain towards glyceraldehyde²².

The situation is quite different for the α 47 mutation. Neither α_1 47 nor α_2 47 is involved in intra double strand contacts¹, but in both cases substitution of the normal aspartate by a histidine

changes the stability of the fibre (Table 3). The observed effects must therefore be due to contacts between the double strands. Since these results thus identify two separate regions on the tetramer, (α_1 47 and α_2 47) as being involved in inter double-strand contacts, they provide much needed constraints for the orientation of the double strands within the HbS fibre. It was shown earlier that the presence of this mutation in both α chains of a HbS tetramer leads to fibres with a loss of two specific pairs of strands, 'capped' by a ring of 16 new strands¹¹. Hopefully electron microscopy of the *cis* and *trans* isomers will resolve the question of the relative roles of the mutation in the two different α chains in causing these structural alterations.

We thank Drs Richard Crepeau and Stuart Edelstein for providing us with the micrographs of native and cross-linked HbS, Drs Stuart Edelstein and Jonathan Greer for helpful suggestions and comments, and especially Dr J. S. Wilkenfeld for gifts of blood containing haemoglobin Sealy. This work was supported by NIH grant HL-17552 and NSF grant PCM-7911610.

Discovery of a very red nucleus in the radio elliptical IC5063 (PKS2048-57)

D. J. Axon*, Jeremy Bailey† & J. H. Hough‡

We report here the discovery of an extremely red IR source in the nucleus of the elliptical galaxy IC5063 (PKS2048-57). The observed (2.2-3.8) μ m colour index within a 5 arc s aperture is 2.1 mag while the colours at shorter wavelengths and in the 5-10 arc s annulus around the nucleus are close to those of normal elliptical galaxies. The IR excess could arise from a BL LAC type nucleus with a steep non-thermal spectrum ($\alpha \sim -4.5$ defined by $F \propto \nu^\alpha$), similar to the recently identified 'red QSOs' typified by 1413+135 (refs 1, 2).

Low luminosity BL Lac objects are predominantly associated with the nuclei of elliptical galaxies which possess flat radio spectra for example, Mkn 421 (refs 3, 4). Many of the nearby E/S0 galaxies have similar radio properties, suggesting that they may also contain nuclei of this type^{5,6}. There are, however, good observational reasons for suspecting that most of this population would not have been recognized as BL Lac objects. The presence of a nuclear source embedded in a bright elliptical galaxy could be almost completely hidden in the visible and near IR by the stellar component. This would arise either

because it was of low luminosity like Mkn 421 or if it had a steep non-thermal spectrum similar to 1413+135, even if the spectrum only steepened at much shorter wavelengths. As most interest has centred on the stellar populations of elliptical galaxies there has been little attention directed at wavelengths longer than 2.2 μ m where radiation from the nuclei is expected to dominate.

NGC1052 is probably the best known example of a radio elliptical which could fit into this category with its large 10- μ m excess⁷ and its recently observed near IR polarization⁸. Other galaxies whose excess 10- μ m fluxes⁹ may qualify them as objects of this type are M87, NGC3894 and NGC4552.

The existence of 'BL Lac' nuclei in the class of active gas-rich ellipticals would be particularly important. These ellipticals are characterized at one extreme by the galaxies NGC1052 and PKS0349-27, which show shock excited line spectra^{10,11} and IC5063, PKS2158-380 at the other, whose optical spectrum is more likely to be due to photoionization by a non-thermal nuclear source^{12,13}. A detailed knowledge of the shape of the non-thermal spectrum of the nuclei of these galaxies would be a vital step in understanding both the physical processes at work in them, and their relationship to the origin of radio galaxies.

Observations of IC5063 and the three other active ellipticals mentioned above (NGC1052, PKS2158-380 and PKS0349-27) were obtained on 16 December 1981 using the IR photometer on the 3.9-m Anglo-Australian telescope. Photometry at J (1.20 μ m), H (1.64 μ m), K (2.2 μ m) and L (3.8 μ m) was obtained through 5 and 10 arc s circular apertures. In all cases the galaxies were centred in the beam by maximizing the 1.2 μ m signal. A chopper throw of 12 arc s in a north-south direction was used.

The results of the photometry are given in Table 1, together

Table 1 Observed K magnitudes and IR colours of the four active ellipticals

with the calculated magnitudes and colours within the 5-10 arc s annulus surrounding the nucleus. The colours (on the AAO-Johnson system¹⁴) of normal elliptical galaxies¹⁵ are given for comparison.

Clearly the colours of PKS2158-380 and PKS0349-27 are very similar to those of normal elliptical galaxies, whereas the results on NGC1052 show the excess IR radiation in the nucleus which has been reported previously⁷.

However, IC5063 shows a very much larger ($K-L'$) colour of 2.1 mag within the 5 arc s aperture, while its ($J-H$) and ($H-K$) colours are close to those of normal ellipticals. This indicates the presence of a very red source which begins to dominate the light of the galaxy only at wavelengths longer than $3 \mu\text{m}$. Furthermore, the colours measured for the 5-10 arc s annulus do not show the large excess, implying that it predominantly originates within the 5 arc s aperture. The ($K-L'$) colour of the annulus is slightly larger than those of normal ellipticals, but a combination of aperture misplacement and seeing could cause a slight spillage of light from the nucleus outside our 5 arc s aperture, so we regard these data as being consistent with a compact source for the IR excess.

We have used two methods to attempt to separate the colours of the IR source from the stellar component of IC5063. First, because the IR colour gradients in normal elliptical galaxies are small¹⁵, we can assume that the ratio of the flux from the stellar component in the 5 arc s aperture and the 5-10 arc s annulus is the same at all colours. Assuming the contribution of the nucleus is negligible at J , we can then estimate the stellar contribution within the 5 arc s aperture for each colour (see Table 2).

The second method is shown in Fig. 1, which is a plot of the observed colours in the form of a flux ratio diagram^{4,16}. On this diagram the observed colours must lie on a straight line joining the colours of the component sources. The colour of the nucleus must therefore be on the line through the 5 and 10 arc s points. A further assumption about the nature of the sources spectrum is needed to define its colours uniquely. The two natural choices for the nuclear spectrum are, non-thermal radiation represented by a power law $F_\nu \propto \nu^\alpha$, and re-radiation by hot dust in the form of a black-body spectrum; although a range of dust temperatures can mimic a power law. For a true power law spectrum the intersection of the line with the locus of possible power law spectral indices, α , indicates a value for α of ~ -4.5 , whereas in the case of a black body, by a similar procedure we find that its colour temperature is $\sim 650 \text{ K}$. If the IR excess is non-thermal in origin this analysis shows that the nuclear source has an extremely steep spectrum, similar to those observed in NGC1052 and the red QSOs. The spectrum of NGC1052 is much shallower, $\alpha = 1.7$ longward of $3 \mu\text{m}$, but must steepen to at least $\alpha = -2.7$ below $2.2 \mu\text{m}$ to account for its weakness in the optical⁸. The spectra of the red QSOs also start shallower

than observed in IC5063 but again steepen rapidly to $\alpha \sim -3$ below $5 \mu\text{m}$ (ref. 17). Observation of these objects^{1,2,18} and brighter flat spectrum sources¹⁹ have shown that they possess many of the characteristics of BL Lac objects. The detection of appreciable linear polarization in 1413+135 (ref. 1) strongly supports their identification as steep spectrum BL Lac objects and the rapid steepening of their spectra has been convincingly explained as a sudden high energy cutoff in the distribution of synchrotron emitting electrons^{1,2}. If the luminosity range of the red QSOs approaches that of normal BL Lac objects then we might expect to find low luminosity counterparts to Mkn 421 in nearby elliptical galaxies. The nuclear IR source in IC5063 may well be just such an object.

The alternative possibility of emission from hot dust arises because the Wein tail of a black body curve can readily mimic a steep spectral index source. This explanation has proved very attractive for the IR continua of Seyfert galaxies as it avoids the physical problems associated with producing the observed spectral changes with non-thermal spectra^{20,21}. Inspection of the SRC Southern Sky Survey shows there is dust in IC5063 which could be heated by the intense UV source invoked as the origin of the photoionization of the gas. However, the high excitation of the gas at large distances from the nucleus argues that the UV source cannot be obscured as heavily as a typical Seyfert nucleus. With the limited range of our data we cannot rule out either option directly although we find the need for an alternative mechanism is capable of producing steep spectrum sources far less compelling since the discovery of the red QSOs. Observations of variations in the near IR with time scales of the order of a day would indicate the presence of a non-thermal source. Another test to distinguish between the

Fig. 1 Flux ratio diagram plotting the ratio of flux at H ($1.64 \mu\text{m}$) to K ($2.19 \mu\text{m}$) against ratio of fluxes at L' ($3.8 \mu\text{m}$) to K ($2.19 \mu\text{m}$). On this diagram, the point representing a composite object must lie on the straight line joining the colours of the two component sources. We have plotted the observed points for IC5063 in 5 and 10 arc s apertures and in the 5-10 arc s annulus (marked A). These points represent varying contributions from the elliptical galaxy and the central IR source. The line through these points passes through the region of the normal elliptical galaxies when extrapolated to the left. The colours of the nucleus must lie on the same line extrapolated to the right. Thus if the source is a power law it must have $\alpha \sim -4.5$. If it is a black body it must have $T \sim 650 \text{ K}$. The colours deduced for the nucleus given in Table 2 are also marked (N). The approximate position of the very red QSO 1413+135 is marked. This source lies below the power law line as its spectrum is becoming less steep by $3.5 \mu\text{m}$.

Table 2 IR colours of the stellar and nuclear components of IC5063

	5–10 arcs annulus	5 arcs aperture	Mag. of galaxy inside 5 arcs (assumed)	Mag of central IR source
<i>J</i>	12.45	12.72	12.72	—
<i>H</i>	11.65	11.80	11.92	14.3
<i>K</i>	11.34	11.32	11.61	12.89
<i>L'</i>	10.62	9.17	10.89	9.41

two alternatives in IC5063 would be IR polarimetry. The presence of significant linear polarization in the IR would firmly establish the non-thermal origin of the continuum. It is also important to determine the shape of the spectrum at longer wavelengths to search for either evidence of re-radiation by warm dust or the flattening which characterizes the continuum of BL Lac objects. If the IR source is non-thermal in origin then its spectrum must flatten dramatically towards the UV if it is to be responsible for photoionizing the gas. We should also stress that our observations do not preclude the existence of bright non-thermal nuclei in PKS2158–380 and PKS0349–27 provided their spectra steepen at longer wavelengths than in IC5063.

Similar observations for a complete sample of radio ellipticals would establish the frequency of this type of nucleus.

We thank Bob Fosbury and Bill Sparks for stimulating our interest in this class of galaxy, and David Aitken for valuable discussions about the IR spectra of active galaxies, also the technical staff of the Anglo-Australian observatory for support and SERC for funding these observations. J.B. is the recipient of an SERC fellowship.

The source of Saturn electrostatic discharges

D. R. Evans*, J. H. Romig*, C. W. Hord†, K. E. Simmons†, J. W. Warwick* & A. L. Lane‡

* Radiophysics Inc., 5475 Western Avenue, Boulder, Colorado 80301, USA

† Laboratory for Atmospheric and Space Physics, University of Colorado, Boulder, Colorado 80309, USA

‡ Jet Propulsion Laboratory, California Institute of Technology, Pasadena, California 91109, USA

During both Voyager encounters with the saturnian system, the Planetary Radio Astronomy (PRA) experiment detected strong discrete episodic bursts of radio emission, termed Saturn electrostatic discharges (SED)^{1–3}. An examination of Voyager 2 photopolarimeter (PPS) data now reveals a narrow feature (possibly a gap) in Saturn's B ring. A single, unique object appears to be responsible for both the SED and this feature.

Fig. 1 Optical thickness of 5,000 km of the outer B ring at 2,650 Å (300 Å bandwidth), as determined by the Voyager 2 photopolarimeter during the Delta Scorpii occultation. The optical thickness is calculated from the number of counts received at the instrument in a given 10-ms sample time.

The episodic nature of SED was well defined at both Voyager 1 and Voyager 2 encounters, the mean period being 10 h 10 ± 5 min and 10 h 11 ± 5 min, respectively, after spacecraft motion was taken into account. The simplest, but by no means only, explanation of this episodic behaviour is that the SED source is an object in a circular, equatorial orbit 107,990–109,200 km from the centre of Saturn. For this hypothetical object to be the source of SED, it must be distinct from its environment by virtue of physical, chemical and/or electrical properties. Such an object should have an effect on surrounding ring material. Indeed, both the Voyager 2 high-resolution (100 m) photopolarimeter and the lower-resolution (~5 km) imaging aboard both spacecraft show remarkable features in this region of the rings.

The PPS occultation data, which are taken at a wavelength of 2,650 Å, show a relatively opaque region from 105,000 to 110,000 km within the B ring (Fig. 1). This region has a mean optical depth in excess of 1.8; however, embedded within this part of the B ring there is a single feature ~150 m wide in which the apparent optical thickness is much less than this value (Fig. 2). This feature is located at $108,942 \pm 6$ km [based on a best fit to experimental values of the Saturn pole position by J. Holberg (personal communication)]. The apparent optical depth in the middle of the feature is 0.15. Like all experimental measurements, this number has an associated error; we calculate that the true optical depth at this point is less than 0.50, with 99.5% certainty. In fact, due to the finite instrument response time and thickness of the ring at this point, these numbers are very much upper limits; the data are certainly not inconsistent with a narrow region of much lower optical depth. To ascertain the reality of this feature, as opposed to the possibility of a statistical fluctuation occurring in the PPS instrument, we have plotted the frequency distribution of the PPS counting rate for 48,000 points in the vicinity of the feature (Fig. 3). The number of counts recorded by the PPS instrument in a given 10-ms sample is proportional to the number of photons received at the instrument in that time. The recorded number of counts is thus related to optical thickness in a logarithmic manner.

The frequency distribution displayed in Fig. 3 has a mean of 11.745 counts and a standard deviation of 3.2935 counts. For comparison, Fig. 3 also shows a gaussian curve with these parameters. Generally, the two curves agree closely, except in the wings. Using this gaussian as a model, we can at least estimate the probability that the feature is produced by statistical fluctuation, within an order of magnitude or so. The feature comprises two adjacent points, with readings of 40 and 25 counts. The combined probability of obtaining two such adjacent points is of the order of 10^{-22} . We have nearly 48,000 possible adjacent pairs, so the probability of obtaining the

observed result by chance somewhere in the data is about 10^{-17} ; even allowing for the lack of accuracy in the model gaussian, this result clearly shows that the feature is almost certainly not statistical in origin. In addition, we have examined over 100,000 independent data points taken by the PPS instrument in its occultation mode at other times, and we find no trace of a similar event anywhere in this enormous data set.

A second peak, of 30 counts, is also visible in Fig. 1. Applying similar statistics, we obtain a probability of 5×10^{-4} of chance occurrence. However, in this instance, only a single data point is significantly different from background values, and, as we have already noted, the gaussian model does not fit the data exactly in the wings, so we feel that this second feature may well be statistical in origin.

The PPS occultation data therefore indicate that at a radial distance of $\sim 108,942$ km there is a region of lowered optical thickness some 150 m wide. As our best estimate of the optical thickness in the middle of the feature is 0.15, we believe that it is reasonable to describe the feature by the term 'gap'.

The radial distance of $108,942 \pm 6$ km corresponds to an orbital period of $10 \text{ h } 9 \text{ min } 4 \text{ s} \pm 3 \text{ s}$ (J. Anderson, personal communication), after planetary oblateness is taken into account. This level of accuracy of period determination permits us to combine unambiguously the Voyager 1 and Voyager 2 SED databases, thus providing an effective baseline of some 290 days from which to estimate the period of the SED source. The PRA data alone provide us with a 'comb' of possible periods with 'tooth' separation of ~ 54 s. If we assume that the SED source may be uniquely identified with the PPS gap, the PPS data should permit us to identify a particular tooth which is consistent with both experimental results. We have indeed found that the data identify a tooth with a period of $10 \text{ h } 9 \text{ min } 12 \text{ s} \pm 6 \text{ s}$, which is consistent with the orbital period above. It is reassuring that the two different sets of data are consistent with a single period, although this fact cannot be described as statistically significant, as the chance probability of this being possible is quite high— $12/54$, or $\sim 22\%$. Bearing in mind our previous argument concerning the uniqueness of the SED source, we believe that it is highly likely that there is a single cause of both SED and the PPS occultation gap observation.

In addition to the PPS data, Voyager images of this region show two intense azimuthal bands which appear bright in forward scattered light, indicating that they comprise a local enhancement of the micrometre-sized dust population, which is ubiquitous throughout the outer two-thirds of the B ring. These bands are each roughly 300 km wide and are $\sim 2,000$ km apart. Although it is true that unusual features are to be seen on Voyager images throughout this region, these two bands are

Fig. 2 Detailed structure of the B ring near the large spike in Fig. 1; this structure indicates a narrow (~ 150 m) gap of low optical thickness.

Fig. 3 Occurrence frequency versus counts for 48,000 data points obtained in the region shown in Fig. 1. Experimental data are shown dotted. The solid line is a gaussian with mean 11.745, s.d. 3.2935.

the most prominent features in wide-angle images of this part of the ring system. Furthermore, enhanced colour images of the ring system indicate a change in particle population characteristics at or near the region in question. This change, and indeed the very existence of micrometre-sized dust in the outer B ring, may be a direct result of the presence of the object and/or the associated SED.

Voyager 2 also carried a UV spectrometer which was boresighted with the PPS instrument and simultaneously observed Delta Scorpii in the range $900\text{--}1,700$ Å. This spectrometer failed to detect any reduction in optical depth at the PPS gap location (with 99.9% confidence) (J. Holberg, personal communication). It is possible that the 'gap' is in fact populated with small Rayleigh scatterers (of the order of ≤ 100 Å in diameter; several theories indicate that there may be substantial numbers of such scatterers in the rings—see, for example, ref. 4). Whether or not this is the true reason for the UV spectrometer null result, the observation that the optically dense outer B ring seems capable of sustaining a very narrow gap (at least to $2,650$ Å radiation) is important in developing a theoretical understanding of the ring.

Thus, Voyager PRA and PPS data indicate the presence of a single, unique object in the B ring at a distance of $\sim 108,942$ km from the centre of Saturn. This object exerts an influence on material adjacent to its orbit, resulting in the formation of a 150-m gap along that orbit. In addition, Voyager imaging data suggest that the object may influence micrometre-sized dust hundreds of kilometres away. The interaction between this object and its environment seems to be the source of SED.

STARE observations of long discrete echoes

E. Nielsen*, G. Sofko† & W. I. Axford*

*Max-Planck-Institut für Aeronomie, D-3411 Katlenburg-Lindau 3, FRG

†University of Saskatchewan, Saskatoon, Saskatchewan, Canada S7N 0W0

Early studies of auroral radar echoes by Unwin^{1,2} showed the existence of a particular class of 'long discrete' echoes, distinguished as being weak and relatively long-lasting (1–60 min). The backscatter usually consists of several narrow (~20 km) bands which drift slowly in latitude, and the height of the backscattering region appears not to exceed 100 km. Here, we report on observations of this type of radar aurora made during the past few years with the Scandinavian Twin Auroral Radar Experiment (STARE). Whereas Unwin's observations covered the range of geomagnetic latitudes corresponding to I -values ~3–5, the present study is concerned with higher latitudes, corresponding to the range $I \sim 5.7$ –8.

The STARE system³ provides measurements of the backscatter intensity and irregularity drift velocity over a large area (~200,000 km²) with good spatial resolution (20 × 20 km²) and a temporal resolution of ~20 s. The twin radar system permits Doppler velocities of E-region ionospheric irregularities to be measured stereoscopically. Aliasing around the time base is avoided by the use of a low pulse repetition frequency (0.05 Hz). Measurements from a given volume of space are combined to yield the irregularity drift velocity vector, assuming that the Doppler velocity measured in a given direction equals the component of the irregularity velocity in that direction. The operating frequencies of the two radars are ~140 MHz, so that they are sensitive to irregularities with wavelengths of the order of 1 m. The system has an automatic gain control which is adjusted to the strongest backscatter detected; thus regions of relatively weak scatter cannot be detected in the presence elsewhere of regions of strong signal-to-noise ratio, which, of course, can effect the apparent probability of occurrence of the former.

The characteristics of the long discrete auroral radar echoes, as observed by STARE, are as follows: (1) On a range-time-intensity plot (Fig. 1a) the echoes appear as a series of striations

which may persist for an hour or more (time interval II in Fig. 1a). (2) The striations are rather straight and are narrow in range (~20–100 km) in contrast with the spread, diffuse appearance of the more intense backscatter associated with strong auroral activity (time interval I in Fig. 1a). (3) The backscatter intensities are weak, with a typical signal-to-noise ratio of only a few decibels. (4) The speed of the irregularities as obtained from Doppler measurements (0–400 m s⁻¹) and the speeds of the apparent motions in range of the backscattering regions (100–300 m s⁻¹) are much smaller than the speeds usually associated with radar aurora (~300–3,000 m s⁻¹). (5) The echoes commonly occur following periods of intense radar auroral activity associated with magnetic disturbances, as indicated in the Fig. 1. (6) The echoes appear to be most prevalent in the early morning and late afternoon hours and in winter rather than summer.

The clear distinction between the properties of intense radar aurora occurring during disturbed periods and the long discrete echoes is evident in Fig. 1b, c where the distributions of the signal-to-noise ratio (SNR) and Doppler-determined velocity (speed and direction) are shown for the intervals I and II. It is evident from Fig. 1b that the backscatter intensity of discrete echoes (average SNR ~5 dB) is in general much less than that from ordinary radar aurora (average SNR ~18 dB). As emphasized above, discrete echoes might also be present in interval I but they would be masked in the presence of the more intense and diffuse radar aurora associated with very active periods and as a result of the automatic gain control of the STARE receivers.

There is a very clear difference in the speed distributions between intervals I and II, shown in Fig. 1c. During the strongly disturbed period, which includes interval I, the observed speed distribution shows an almost complete cut-off at speeds below 300 m s⁻¹, whereas in the period dominated by discrete echoes the average speed is only 150 m s⁻¹ and hardly ever exceeds 300 m s⁻¹. It is interesting that during interval II in Fig. 1 the speed of the polewards motions of the backscatter striations is comparable with but not exactly the same as those obtained from the simultaneous Doppler measurements. The angular distribution of the Doppler velocities measured during the two intervals is shown in Fig. 1c; in interval I the directions lie in the sector 0–90° east of north with a maximum at ~75°; in contrast, the angular distribution during interval II is much broader, being predominantly northwards but with deviations of 70° and more, both east and west of north.

The diurnal and seasonal distributions of the occurrence of discrete echoes observed during 5 yr between 1977 and 1981 are shown in Fig. 2. It is clearly evident that this type of radar

Fig. 1 a, A range-time-intensity plot showing ordinary radar aurora and long discrete echoes detected by a single narrow antenna beam pointing 24.5° E of geographic north (beam B). The signal in time interval I is representative of the radar aurora associated with auroral electrojet activity. The striated appearance of the record in interval II indicates the presence of long discrete echoes. b, Statistical distributions of the signal-to-noise ratios measured during intervals I and II. The long discrete echoes are significantly weaker than the ordinary radar aurora. c, Distributions of the irregularity drift speeds and directions in intervals I and II. The long discrete echoes have drift speeds which are less than the threshold of the two-stream instability (arrow).

aurora is almost entirely confined to periods of EUV 'darkness' at E-region altitudes and is predominantly an early morning phenomenon. Note, however, that the presence of intense backscatter would tend to mask the presence of any discrete echoes during the period 2000–0200 h and hence there is a possible bias in the diurnal distribution.

The most remarkable feature of the discrete echoes is the speed distribution. It is usually assumed, on the basis of linear instability theories of plasma processes occurring in the auroral ionosphere, that the Doppler velocities determined by STARE measurements are essentially the same as the electron drift velocities and hence provide a measurement of the E-region electric field^{4–6}. The two-stream instability⁷ is the most likely candidate for producing the density irregularities observed to occur in regions of strong auroral zone electric currents such as observed during interval I, for example. However, this instability has a threshold such that the electron drift speed relative to the ions must exceed the ion sound speed, which is typically 300 m s^{-1} (equivalent to $\sim 15 \text{ mV m}^{-1}$). The speed distribution observed during the period of occurrence of discrete echoes shown in Fig. 1c, is clear evidence that the electron density irregularities cannot be due to the two-stream instability. Because we do not know the nature of the electron density irregularities we cannot assert that the measured apparent speeds represent electron drift speeds and hence they may not necessarily constitute a measurement of the ionospheric electric field strength.

It is possible that the electron density irregularities associated with striated radar aurora are due to an instability other than the two-stream instability, for example the gradient-drift instability⁸. However, to produce this instability with an eastwards directed electric field a strong eastwards directed electron density gradient is required. This is difficult to accept in view of the fact that the striations are evidently narrow in north-south extent and persist for upwards of an hour. The length scales involved ($\sim 20 \text{ km}$) do not in any case suggest that the electron density gradient is large.

It is difficult to argue that the electron density irregularities which produce the discrete echoes observed by STARE are associated with magnetospheric effects. A mapping to ionospheric levels of small-scale magnetospheric motions (or, equivalently, electric fields) must be ruled out as a possible cause of the irregularities because for such small-scale lengths perpendicular to the magnetic field, as required in this case, the mapping is quite ineffective⁹. It is also unlikely that the source of the ionization produces electron density irregularities of the required scale directly, as the gyroradii of electrons with energies of the order of 10 keV (necessary to penetrate to altitudes of $\sim 100 \text{ km}$) are $\sim 10 \text{ m}$, which is much larger than the irregularity scale size required. It is also conceivable, however, that a combination of a strongly inhomogeneous source distribution and the gradient drift instability, together with some cascading in irregularity scale could be effective¹⁰.

If the discrete echoes are associated with enhanced electron precipitation it is conceivable that the irregularities are due to unstable electron velocity distributions resulting from a relatively high density of secondaries. If the secondary electron distribution function is indeed unstable, such irregularities should be present in all regions of intense electron precipitation, especially around arcs; in general an anticorrelation of backscattering and precipitation regions is observed (G. Keys and M. Scourfield, personal communication), although this could be affected by the automatic gain control in the STARE system. Such an explanation would be consistent with the slow, polewards drift observed in the early morning post-substorm aurora¹¹; however it is not obvious that field-aligned irregularities can be produced at relatively low altitudes by this means.

In view of the fact that both the magnetospheric and ionospheric explanations for the origin of the irregularities producing the discrete echoes are not completely satisfactory, it is interesting to consider whether or not an atmospheric origin is a

Fig. 2 The diurnal and seasonal occurrence of long discrete echoes. Contours of constant solar elevation ($0^\circ \pm 10^\circ$) in the middle of the STARE field of view are shown and indicate that the discrete echoes are not present, within the limits of the system sensitivity, for solar elevation angles $\geq 10^\circ$. ---, -10° ; —, 0° ; ····, 10° .

possibility. In this case, the echoes would be similar to those observed by mesosphere-stratosphere-troposphere radars such as the SOUSY system¹². The electron density irregularities are then most likely to be the result of an interaction between turbulent motions of the neutral gas and steep electron density gradients, although other processes such as density fluctuations associated with the turbulence itself, which produce corresponding fluctuations in the electron density (by entrainment or as a result of the ionizing processes), are also possibilities^{13–15}. In this case however, the backscatter must occur at much lower altitudes than usually assumed to be the case for radar aurora, as the STARE scattering scale length of $\sim 1 \text{ m}$ is equal to the mean free path in the neutral atmosphere at an altitude of $\sim 112 \text{ km}$. To produce a reasonable level of fluctuations in the neutral density the mean free path should be $\ll 1 \text{ m}$, which suggests that the scatter should originate at altitudes $\leq 100 \text{ km}$, and even then the length scale would lie in the viscous subrange of the atmospheric turbulence. This explanation has certain attractive features, notably that it does not require a velocity threshold and, indeed, the observed speeds are comparable with the speeds of atmospheric motions. To test this hypothesis it will be necessary to determine more accurately the height of the region from which the echoes come, which, according to Unwin^{1,2}, is "100 km or less".

The disappearance of E-region irregularities after sunrise could be explained as a consequence of an enhanced recombination rate. It can be shown that the decay time of an irregularity is $1/2\alpha\bar{n}$, where α is the (dissociative) recombination coefficient and \bar{n} the mean electron density. As \bar{n} may increase by a factor of 10 or more after sunrise, it is clear that the effects of any source of electron density fluctuations must be strongly suppressed in such circumstances. However, if the irregularities occur at much lower (D-region) altitudes, this argument is not necessarily correct, because photodissociation of negative ions may have an important role during sunrise. In this case the disappearance of the echoes would be more easily accounted for on the basis of a complete change in the electron density profile as well as a possibly enhanced loss rate.

To make further progress in understanding the phenomenon of discrete radar echoes in the auroral zone, further observations are required. For example, it will be necessary to determine whether or not striations as shown in Fig. 1 correspond to regions of enhanced optical emission and enhanced ionospheric plasma density. The latter can be determined using the EISCAT system, now being brought into operation, and this will also allow us to determine whether or not the Doppler velocities measured by STARE are related to electric field drifts. More extensive latitude coverage will also be required,

for example, to determine the relationship of the discrete echoes to phenomena occurring near the auroral electrojet. This is now possible using STARE together with the new SABRE system, which is similar to STARE but operates in a lower latitude range ($4.2 \leq l \leq 5.6$).

Finally, direct measurements of the altitude of the echo-producing irregularities should be possible by using the partial reflection system existing at the EISCAT site and other backscatter radars which are available, including the EISCAT VHF system.

Recent developments in the use of nuclear accelerators as high-energy mass spectrometers^{1,2} has renewed interest in the study of cosmogenic ^{10}Be (half life 1.5 Myr) as a geophysical time tracer. The accelerator techniques enable us to measure ^{10}Be with a sensitivity of 10^7 atoms or less. The potential age dating span with ^{10}Be is extended back to at least 15 Myr BP, providing that the ^{10}Be production and deposition rates remain constant or nearly constant over that time period. A knowledge of the long-term constancy in the ^{10}Be deposition rate is thus very important. We report here the first detailed measurements of ^{10}Be and ^9Be in two ferromanganese oxide crusts from the sea floor of the equatorial Atlantic (sample no. K-9-21) and the North Pacific (SCHW-1D), each representing >10 Myr of accumulation history. We have found in these crusts that the deposition of ^{10}Be and $^{10}\text{Be}/^9\text{Be}$ during the past 7–9 Myr has been constant. Averaged over time intervals of ~1 Myr, the variation is within $\pm 6\%$. Before that time, both crusts show similar significant deviations. The 7–9 Myr demarcation may be related to the reported late Miocene global abyssal circulation change in the ocean³.

The extent of variation in the oceanic deposition rate of ^{10}Be during the past 2.5 Myr has been assessed based on the ^{10}Be distribution in sediment cores^{4,5}. An upper limit of $\pm 10\%$ has been placed on the variation when the deposition is integrated over time periods of $2\text{--}7 \times 10^5$ yr. For shorter periods of 1×10^5 yr (roughly corresponding to climatic cycles), the limit is placed⁵ at $\pm 30\%$. The record can be extended by examining ^{10}Be distribution in deep-sea ferromanganese deposits as these materials, in addition to being relatively free of terrestrial detrital input, contain very long depositional records due to their slow accretion rates⁶. Manganese crust K-9-21 was

dredged from a fracture zone scarp on the Sierra Leone Rise. It rested on an altered foraminifera ooze. The substrate of SCHW-1D was a large basaltic rock. These crusts were chosen over the more commonly occurring manganese nodules for the study because the crusts were: (1) relatively flat, so that sampling of contiguous layers perpendicular to the growth axis could be accurately done; (2) fixed in their growth position with respect to top and bottom orientations relative to the sea floor.

Thin layers parallel to the growth surface were carefully taken throughout the whole thickness of the crusts for analyses of ^{10}Be , ^9Be , Mn, and Fe. The thickness of each layer was estimated using caliper and/or from the area, weight and density of material scraped off⁷. In the accelerator analyses of ^{10}Be , milligramme-to-gramme-sized samples were leached with hot 8 M HCl, and then to the leachate was added a $^9\text{BeSO}_4$ carrier (equivalent to 1–10 mg BeO). A simplified version of the procedures of Ku *et al.*⁸ involving only the ion exchange steps was used in the separation of Be from the leachate, as strict chemical purity is not required by the accelerator technique. Measurements of $^{10}\text{Be}/^9\text{Be}$ were carried out using the McMaster University tandem Van de Graaff accelerator modified for this purpose⁹. The sensitivity achieved was $\sim 5 \times 10^{-13}$, and background intensities from reagent blank runs were <10% of the weakest sample signals measured. Mn, Fe and total Be were measured by atomic absorption spectrophotometry; to measure Be, flameless atomization with a deuterium background corrector was used.

The analytical results are presented in Table 1, with errors shown as $\pm 1\sigma$. For Mn and Fe, the measurement precisions are about $\pm 1\%$. The concentration values are listed on a residue-free basis, as the Mn, Fe, and Be will be mainly associated with the HCl-leachable oxide phase of the crusts²⁴.

The temporal variation of ^{10}Be deposition can be assessed by examining the depth distribution of ^{10}Be and the other chemical constituents. As the major constituents in ferromanganese deposits, Mn and Fe are often anti-correlated, and their ratios can be used as a measure of chemical and growth rate variability^{10,11}. In this regard, the two samples studied both show narrow limits of variability. As seen in Table 1, concentrations of Mn and Fe in the two specimens are comparable and show variations of about $\pm 10\%$, with Mn/Fe ratios ranging only from 0.7 to 1.0. Except for the low values in surface layers of SCHW-1D, ^9Be also shows minor temporal fluctuations of about $\pm 10\%$. These narrow limits of variation suggest overall uniformity in the deposition of the two crusts. The log-linear distribution of ^{10}Be shown in Fig. 1 supports this uniformity: the straight lines are weighted least-squares fits to an exponential function, as obtained through iterations¹². The effective measurement depth for each sample is calculated iteratively to account for the radioactive decay taking place during the deposition period represented by each sample interval. The fittings are made over the 'linear' segments of the plots (see legend to Fig. 1), covering major portions of both samples. The slopes of the straight-line fits, which yield accretion rates for the crusts, have standard errors of $\pm (4\text{--}7)\%$ (averaging $\pm 5.5\%$). These errors denote the scatter of data about an exponential curve, and therefore limits the constancy of the ^{10}Be flux and of the flux ratio ^{10}Be to ^9Be into the deposits.

Both the growth rate (~ 1.5 mm Myr) and the Mn/Fe ratio (< 1) are near the lower end of their reported ranges of values for Mn nodules^{6,11}, suggesting minimum influence of diagenesis as a source for Mn. The crusts have received $\sim 2 \times 10^4$ atoms $\text{cm}^{-2} \text{yr}^{-1}$ of ^{10}Be , which is $\sim 4\%$ of the global average ^{10}Be production rate^{13,14}. A similar situation applies to the Mn inventory: $\sim 0.05 \text{ mg cm}^{-2} \text{Kyr}^{-1}$ in the crusts compared with $1.3 \text{ mg cm}^{-2} \text{Kyr}^{-1}$ as the average Mn flux into 38 deep-sea cores¹⁵. Thus most of the ^{10}Be and Mn must have deposited in the adjacent sediment, or the accretion process is not continuous; that is on average, the crusts were actually growing for $\sim 4\%$ of their lifetime^{8,16}.

A decrease of ^{10}Be concentration toward the surface from a near-surface maximum occurs in SCHW-1D (Fig. 1). The

sampling resolution is not sufficient to detect such a feature in K-9-21. But we have found this feature to be rather ubiquitous among the other deep-sea ferromanganese deposits we have studied. This ¹⁰Be 'inversion' occurs at a depth corresponding to ~0.5 Myr in age. Whether it reflects a change in the ¹⁰Be input or a diagenetic phenomenon remains to be resolved. Noting a surface depletion of ⁹Be as well as ¹⁰Be (Table 1), two of us (M.K. and T.L.K. in preparation) have proposed a post-depositional Be fixation process whereby both Be isotopes are released from a labile phase (or phase with exchangeable Be) at the seawater-solid interface and transferred to the oxide phase through diffusion and adsorption reaction in pure fluid.

As pelagic sediment and shale contain only 2-3 p.p.m. of Be (ref. 17), most of the Be in the samples, like many other elements in ferromanganese deposits, must be authigenically precipitated rather than of detrital origin. Recent studies have described the particulate cycling of ¹⁰Be and ⁹Be in the sea¹⁸⁻²⁰. Information on the extent to which the oceanic reservoirs of these two isotopes are equilibrated in time and space is germane to the ¹⁰Be geochronology. If isotope equilibrium is achieved, the use of the ¹⁰Be/⁹Be ratio in lieu of ¹⁰Be concentration would circumvent the latter quantity's being affected by factors other than radioactive decay, such as changes in sedimentary composition and deposition rate. The present data suggest that for periods of the order of 1 Myr the oceanic ¹⁰Be/⁹Be reservoir as well as ¹⁰Be deposition has remained constant to within ±6% for approximately the past 8 Myr (represented by the first 10-13 mm of the crusts; Fig. 1).

It should also be of interest to determine the spatial constancy of the ¹⁰Be and ⁹Be reservoirs. This information would be best obtained from simultaneous measurements of ¹⁰Be and ⁹Be in water columns from various parts of the ocean. But these have yet to be done. A less rigorous alternative would be to compare reported values for the isotope ratio ¹⁰Be/⁹Be (extrapolated to zero age) in manganese nodules and crusts from different areas²¹. These values range over one order of magnitude²². To eliminate any interlaboratory discrepancies, we list in Table 2 the extrapolated ratios in six ferromanganese samples based

on measurements made only at our own laboratories, including the two crusts reported here. The data scatter is outside the experimental uncertainties of about ±15%, suggesting variability of ¹⁰Be/⁹Be with location and water mass. This is plausible, in view of the fact that the residence time of Be in the sea has been estimated¹⁸⁻²³ as being comparable with or shorter than the oceanic overturn time of ~10³ yr. If so, the temporal constancy in ¹⁰Be/⁹Be for the past 7-9 Myr deduced in this study would imply considerable stability (on a Myr time scale) in oceanic circulations during the period. However, conditions before 7-9 Myr BP could be significantly different, as shown by the deviations from the log-linear fits deeper in both crusts (Fig. 1). According to Ciesielski *et al.*³, the abyssal circulation then was very different due to the absence of a true Antarctic Bottom Water similar to that produced today in the Weddell Sea.

The Fig. 1 deviations are such that they can be explained by an approximately twofold increase in the accretion rate of the crust. Although possible, such a large increase seems unlikely considering the following. A near-synchronous accretion rate change occurring in two different major ocean basins would call for events affecting the global supply of Mn and/or Fe, such as changes in submarine hydrothermal activity and sea floor redox condition. And one would expect the samples to show a major change in their Mn/Fe ratio and perhaps ⁹Be

Table 2 Extrapolated (to zero age) atom ratio ¹⁰Be/⁹Be in six ferromanganese deposits

Fig. 1 Depth plots of ^{10}Be concentration (on a residue-free basis) and $^{10}\text{Be}/^9\text{Be}$ in two Mn crusts. Least squares fits for the 'linear' segments of the plots give estimates for the accretion rates (and their standard errors) of the crusts. The linear segment for sample K-9-21 includes the top four data points; for SCHW-1D, data points 6–12 from the crust surface. The horizontal dotted lines denote the depth intervals analysed, and the positions of the vertical lines (error bars) are placed at the effective measurement depths.

and residue concentrations across the 7–9 Myr boundary. We do not discern such a change. We thus favour the possibility that those deviations were caused by a shift in the initial $^{10}\text{Be}/^9\text{Be}$ ratio resulting mainly from a shift in the ^{10}Be input. While the primary atmospheric supply of ^{10}Be might have varied, we consider it more likely that the ^{10}Be input change is related to the modification of oceanic mixing patterns 7–9 Myr ago³, as mentioned above. During that time, the major production of the Antarctic Bottom Water began. This event marks the initiation of the modern global circulation, and has led to shifts in such oceanic properties as carbonate compensation level and carbon isotopic composition³. It could also have influenced the Be records observed here, by exposing the crusts to bottom waters bearing different ^{10}Be contents and $^{10}\text{Be}/^9\text{Be}$ ratios before and after the 7–9 Myr event. Studies of sedimentary deposits (such as Deep-Sea Drilling Project sediments) as well as other Mn crusts would be required to test this possibility further.

We thank J. Kuehner and his staff at the McMaster accelerator for assistance, W. S. Moore and T. Walsh for supplying the samples which were the collections of Lamont-Doherty Geological Observatory (K-9-21) and Scripps Institution of Oceanography (SCHW-1D), C. Measures for checking our ^9Be analyses, and K. Johnson for making available the atomic absorption facilities at the University of California, Santa Barbara. J. Sheppard and N. Bohna assisted in the ^9Be and data analyses. This research was supported by the NSF Manganese Nodule Program (MANOP), by the NSERC of Canada, and by Simon Fraser University.

<33,000-yr K–Ar dating of the volcano–tectonic horst of the Isle of Ischia, Gulf of Naples

P.-Y. Gillot

The Gulf of Naples corresponds to a tectonic sink connected with recent volcanic activity in the South-Campanian area (Phlegrean Fields, Ischia and Vesuvius). At its extreme north-west, the Isle of Ischia was early recognized as a volcano-tectonic horst by Rittmann¹. Previous data² concluded that its uplift ended around 300,000 yr, and that the Green Tuff formation, of which it is predominantly composed, had an age of some 700,000 yr. But tectonic and morphological studies, together with original tephrostratigraphical observations on the slope of the horst, led us to do some new K–Ar datings. These revealed that the 780 m uplift of the horst from the sea level is younger than 33,000 yr; the Green Tuff, which was considered to be the oldest volcanic unit in the island is now dated at 56,000 yr, its eruption following the dismantlement of a first volcanic complex now dated as not older than 130,000 yr.

Rittmann¹ recognized that the principal structure of the Isle of Ischia is a volcano-tectonic horst (Monte Epomeo, 787 m) and not a central volcano as had previously been believed^{3,4}.

The horst of Monte Epomeo is part of a system of faults running north to south and from east to west, describing a quadrilateral between the villages of Lacco Ameno, Casamicciola, Barano and Panza (Fig. 1); it is formed of a trachytic ignimbrite: Green Tuff. Although of subaerial origin, this unit was totally covered by the sea before the uplift of the horst, as attested by the overlay of marine deposits and the existence of diffuse 'glauconite' giving it its green colour. Rittmann considers Green Tuff as the oldest formation found outcropping on the island, on which all the products of subsequent volcanic activity occurring along the horst faults were deposited. K-Ar chronometric studies of volcanic units from the Isle of Ischia have dated Green Tuff at 6.0 ± 0.14 Myr (biotite)⁵ later corrected to 0.7 ± 0.1 Myr (sanidine and biotite)². According to these data, the most important phase in the activity of the island goes back to ~ 0.3 Myr and it would be around that period when the uplift of the horst ended. However, Evernden and Curtis⁶ have obtained a K-Ar dating of 83,000 yr on sanidine from a sample of Green Tuff, and an attempt at U-Th dating the Tuff of Citara^{7,8}, which is the product of an important explosive event of Ischia, gave a probable age of $41,500 \pm 3,000$ yr.

New tephrostratigraphical⁹, tectonic and morphological studies have been undertaken on the Isle of Ischia, as part of the research into the evaluation of volcanic risk in active volcanic regions. They revealed that lava units associated with breccia can be individually identified under the Green Tuff at the foot of the Western slope of Monte Epomeo (Rione Bocca), bearing witness to the existence of a phase of activity before the formation of the Green Tuff. However, they also reveal that the formation of the horst of Ischia is very recent, without doubt still active and directly correlatable with the historical volcanic activity attested by archaeological observations¹⁰ of which the latest manifestation is the Arso lava flow (December 1301–January 1302). The disparity of ages and the new data available prompted us to renew the chronometric study of the main eruptive phases on the island. The techniques used have been described elsewhere^{11,12}. Argon was analysed using a 180° , 6-cm radius, 500 V accelerating potential mass spectrometer operated in the static mode. The sensitivity of the machine was 4×10^9 atoms mV⁻¹ using a $10^{11} \Omega$ resistor in the vibrating reed electrometer. For the ^{36}Ar peak, the output was typically 30–100 mV and the noise level was around 0.03 mV. The accurate correction for contamination necessary when dating such young rocks was obtained by avoiding any discrimination effect in the mass spectrometric measurements, that is, unspiking, and consequent successive measuring of 36 and 40 ion beam intensities for sample argon, atmospheric argon and the standard argon amount in the same working conditions in the mass spectrometer (with $<0.3\%$ fluctuation of any of the parameters—accelerating potential, arc voltage, electron beam current, background of the mass spectrometer with masses other than argon and the amount of argon present in the mass spectrometer when doing the comparison of sample argon with atmospheric argon)¹². In these conditions it is possible to date to within 10,000 yr (refs 12–14) lavas containing 1% of potassium. Therefore Ischia's rocks can be dated to within a few thousand years, being classified between latites and alkali-trachytes with a potassium content of at least 4%. This accuracy corresponds typically to a limit of detectability of 0.2% on the level of radiogenic ^{40}Ar . It makes possible a 10% accurate dating at a contamination level of 98%. Confirmation that such precision of measurement can be attained was provided by analyses of air argon samples measured at the same working point of the mass spectrometer; the uncertainty in $^{40}\text{Ar}/^{36}\text{Ar}$ ratio was $0.12\%/(2\sigma)$ for a single analysis calculated from about 12 runs). Data on 11 samples from historic or radiocarbon dated volcanic units presented in Table 1 reveal a fairly good agreement and confirm the reliability of K-Ar data down to 0.2% of radiogenic argon. Among the analysed samples is one from the Arso flow from Ischia which erupted in AD 1302. Note that the dispersion observed for replicate measurements on the same sample was always within the range of the predicted error.

Sixteen samples of volcanic units of the Isle of Ischia were then dated. They were selected as a function of their stratigraphical position and corresponded to the different activities developed in the island: before the horst uplift, old volcanic remains outcropping on its periphery and volcanic units affected by the faults of the horst; recent volcanic activities developed along the faults of the horst, contemporaneously to the uplift. Ages obtained are reported in Table 2. All these results are in agreement with the available stratigraphical control: the trachyte of the Costa Sparaina (sample 2) flowed over the lava of the Selva del Napolitano (sample 3) both lying on Green Tuff (samples 8, 9) on the eastern flank of the horst; a trachytic block (sample 10) included in the Green Tuff and the lava flow at Rione Bocca (sample 11), overlain by Green Tuff, gave ages slightly older and coherent with other ages obtained for the oldest volcanic units outcropping on the Isle between 130,000 and 75,000 yr; also, samples 4, 5 and 6 corresponding to the products of the Campotese volcano and the Citara pumice level are directly superimposed. Moreover ages obtained on separated mineral phases (sanidine and groundmass) of the same unit, with various potassium contents and various levels of contaminant argon, gave the same ages within the limit of the predicted accuracy. Under the pumice deposit associated with the trachytic lava of Fondo d'Oglio crater (sample 1), which erupted during the historic period according to our K-Ar results ($<2,000$ yr), we have sampled shells in a palaeo-beach level to crosscheck our result with radiocarbon dating. We also found a piece of ceramic indicating that the pumice flowed over historical deposits, in good agreement with our result: this pottery could be attributed to the third century AD (G. Marinelli, personal communication).

Our K-Ar measurements confirm that Green Tuff, $56,000 \pm 4,000$ yr, is not the oldest volcanic formation outcropping on the Isle of Ischia. The dating of volcanic units between 130,000 yr (Castello d'Ischia lava, sample 16, $132,000 \pm 2,600$ yr; Monte di Vezzi lava flow, sample 15, $128,000 \pm 5,000$ yr) and $75,000 \pm 2,000$ yr (dome of Monte Vico, sample 12) shows that volcanic centres were active before the Green Tuff's eruption. These centres correspond to volcanic units which are at present partly dismantled and visible at the

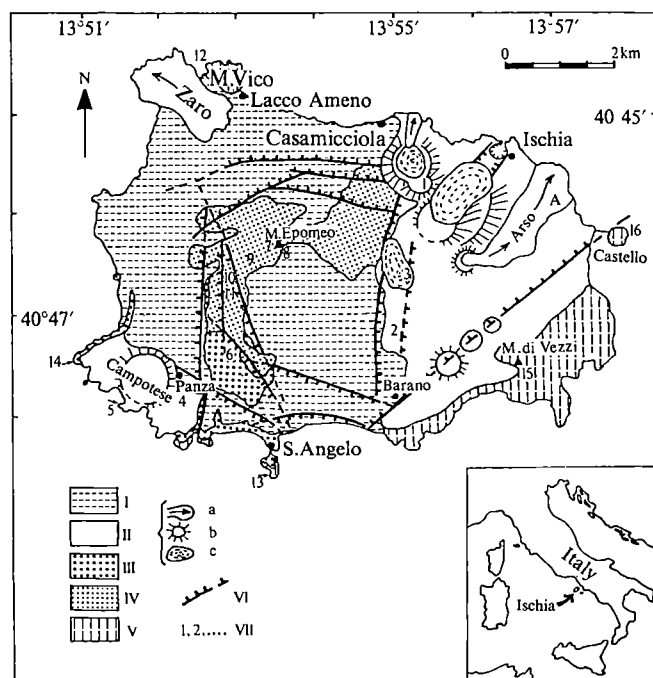

Fig. 1 Geological sketch map of the Isle of Ischia. I, scree and mud flows; II, volcanic units younger than 30,000 yr, a, lava flow; b, crater; c, dome; III, Citara Tuff; IV, Green Tuff of Monte Epomeo; V, formations of the first volcanic complex, dismantled; VI, faults; VII, samples location (same numbers as in Table 2 and the text).

periphery of the Epomeo's horst; this is also the case at Castello d'Ischia in the east, Monte Vico in the north, the peninsula of S. Angelo (sample 13, $97,000 \pm 5,000$ yr) in the south and Monte di Vezzi in the south-east. The first complex probably extended beyond the boundaries of the present island and dating indicates that it was built up over at least 60,000 yr. The major part of the old volcano has indeed been eroded and disappeared following former collapses and the Green Tuff's eruption. In the south-west part of Ischia, near Panza, the recent products of the complex volcanic centre of the Campotese are

superimposed on the remnants of old structures almost completely submerged and outcropping along the coast at Punta Imperatore (sample 14, $118,000 \pm 3,000$ yr), Capo Negro and S. Angelo. A level of pumice (the Citara Tuff) divides the old flows from the recent products of the Campotese⁹. Citara Tuff also overlaps the Green Tuff on the south-west slope of Monte Epomeo, where it is affected by the faults of the horst, and passes laterally into a facies of fine cinerites, which are intercalated with marine deposits. Hence, this pumice level (sample 6, $33,000 \pm 2,000$ yr), younger than the Green Tuff and the

A, Arso flow of Ischia (sample 36 I), drilled in the core of the flow at the international camping of Ischia Porto; B, trachytic dome of Caprara (sample CF 27), connected with Astroni crater, Phlegrean Fields, Campania, Italy; C, Pumice level (sample 36 O), connected with Neapolitan Yellow Tuff, Phlegrean Fields, Italy; D, Campanian Ignimbrite (sample 35 P) sampled at S. Agata dei Goti, Campania, Italy; E, AD 1944 Vesuvius tephritic flow (sample 35 H); F, Obsidian flow of Rocche Rosse (sample 28 X), Lipari Island, Italy; G, Grotta dei Palizzi trachytic flow (sample 38 T) southern flank of modern Vulcano, Aeolian Islands, Italy; H, Punta Frontone shoshonitic flow (sample 37 P) base of modern Stromboli (Filo dell'Arpa), Aeolian Islands, Italy; I, Mount Etna AD 1971 flow (sample 29 C) fine grained light grey facies of the core of the flow; J, Mount Etna (Sicily) sixteenth century AD flow (sample FLG 3) sampled in the quarry of Nicolosia; K, basaltic flow of Puy de la Vache (sample 30A, sampled at St Saturnin, Chafne des Puys, Massif Central, France. The errors are calculated according to:

$$\frac{\sigma^2 \text{Age}}{\text{Age}^2} = \left(\frac{1-T}{T} \right)^2 \frac{\sigma^2 \text{Ar}}{\text{Ar}^2} + \frac{\sigma^2 \text{Cal}}{\text{Cal}^2} + \frac{\sigma^2 \text{K}}{\text{K}^2}$$

where T is the radiogenic argon proportion in total argon;

$$(\% \text{ error in radiogenic Ar})^2 + (\% \text{ error in calibration})^2 + (\% \text{ error in K})^2$$

Its value tends to $\pm 2\%$ when the radiogenic argon level becomes $>10\%$, taking into account a 0.5% (2σ) error on the calibration for a definite value of standards¹⁹ and an error of 1.5% on K content dosed by atomic absorption spectrophotometry. The error in the radiogenic argon was determined using the expression:

$$\left(\frac{1-T}{T} \right)^2 \left(\frac{\sigma^2 r}{r^2} + \frac{\sigma^2 r'}{r'^2} \right)$$

where r and r' are the $^{40}\text{Ar}/^{36}\text{Ar}$ ratios in sample argon and atmospheric argon. This expression is comparable with the formulation in refs 20-22. Because of the steadiness of the different argon signals measured in our machine and because of the simultaneous collection of ^{36}Ar and ^{40}Ar signals, the error in radiogenic ^{40}Ar corresponds to the errors in the measurements of isotopic ratios, and, essentially, to the error on ^{36}Ar measurements. In our case of very low radiogenic level, $r \sim r'$; the error on radiogenic argon can be written:

$$\left[2 \left(\frac{100 - ^{40}\text{Ar}^* \%}{^{40}\text{Ar}^* \%} \times \% \text{ error in } ^{40}\text{Ar}/^{36}\text{Ar} \right)^2 \right]^{1/2}$$

This is the major uncertainty in the calculated age because of the error magnification associated with the small proportion of radiogenic argon found in the analyses ($0-10\%$).

Sample weight: $5-10$ g per argon analysis; $^{40}\text{Ar}^*$ = radiogenic ^{40}Ar ; the following decay constants were used in the ages calculation²³: $\lambda_B = 4.962 \times 10^{-10} \text{ yr}^{-1}$, $\lambda_e = 0.581 \times 10^{-10} \text{ yr}^{-1}$, $^{40}\text{K}/\text{K} = 1.167 \times 10^{-4}$.

Same analytical conditions as presented in Table 1.

ancient lavas of the south and south-west part of the island, was deposited close to sea level before the formation of the horst of Monte Epomeo; consequently the amplitude of this uplift of at least 800 m can be dated back to <33,000 yr. The formation of the horst was accompanied by volcanic activity which developed at its periphery during the past 30,000 yr. In

particular, the north-east sector of Ischia, described by the eastern marginal fault of the horst of Epomeo and by the fault running south-west north-east Barano-Castello, appears to consist of pyroclastics and lavas, recently emitted by domes, explosion craters and spatter cones (for example, Selva del Napolitano lava, sample 3, $9,000 \pm 1,500$ yr; Costa Sparaina trachytic flow, sample 2, $4,000 \pm 1,800$ yr; Fondo d'Oglio trachytic flow, sample 1, $1,500 \pm 1,000$ yr). In this sector, it was possible, by dating, to link an important phase of activity to the prehistoric and historic period. Besides the formation of the flows and the trachytic domes, the pumice layers which extend over the whole eastern sector of the island also originated during this phase. The data from our study indicate that the volcanic and tectonic history of the Isle of Ischia is perceptibly different from that which was previously accepted and reveal the important seismic and volcanic risks in this zone. The age of the volcanic activity of Ischia is much younger than was thought. From ~130,000 yr ago, a first complex was built which was partly eroded and dismantled by a tectonic phase which finished by a collapse, following the eruption of the Green Tuff, dated at $55,000 \pm 3,500$ yr. The uplift of the volcano-tectonic horst of Monte Epomeo is <33,000 yr old, as given by the age of the Citara Tuff. It occurred at the same time that the modern volcanic activity developed.

The study was supported by CNR (Progetto Geodinamica—Rischio Vulcanico) and the Programme Interdisciplinaire de Recherche pour la Prevision et la Surveillance des Eruptions Volcaniques, CNRS. We thank J. Labeyrie and J. C. Duplessy for useful criticism, and Dominick Christie for translating the manuscript.

Unusual distribution of biological markers in an Australian crude oil

R. P. Philp & T. D. Gilbert

CSIRO Division of Fossil Fuels, PO Box 136, North Ryde, New South Wales, 2113, Australia

The stereochemical configuration of hopane-type triterpanes in source rock extracts or crude oils is normally determined by the maturity of the sample¹. Naturally occurring precursors of the hopane hydrocarbons are dominated by the $17\beta\text{H}$, $21\beta\text{H}$ stereochemistry with only one diastereomer at the C22 position in the C₃₁ and higher homologues². Note that the $17\beta\text{H}$, $21\beta\text{H}$ -C₂₈ homologue has never been reported in any sample. Mature crude oils in general contain hopane hydrocarbons dominated by the thermally more stable configuration of $17\alpha\text{H}$, $21\beta\text{H}$ stereochemistry and a mixture of the two diastereomers at the

C22 position for C₃₁ and higher homologues in the ratio of ~3/2. We present here evidence for the presence of an unusual distribution of hopanes in an Australian crude oil. A study by computerized gas chromatography-mass spectrometry (C-GC-MS) designed to determine whether different oils from the same basin have similar sources has revealed the presence of the thermally unstable 17 β H, 21 β H isomers of hopane-type triterpanes in conjunction with C22 diastereoisomers in the unusual ratio of 1:9. We propose that there are two possible explanations for this unusual distribution of the triterpanes. (1) The oil is immature or (2) these compounds have accumulated in the oil as it migrated through coals in the region of the reservoir which are also known to contain the unusual hopane distribution.

Figure 1a, which is a portion of the *m/z* 191 chromatogram obtained from the GC-MS analysis of an Australian crude oil, illustrates the use of the technique of single-ion monitoring (SIM) to determine the distribution of the triterpanes³. This ion corresponds to the A/B ring fragment of the hopane structure shown above. Examination of complete spectra showed that the predominant hopane components in this sample (1, 2, 5-10) all have the 17 α H, 21 β stereochemistry as has been previously reported for crude oils¹. The ratio of the C₃₁ 22S and R isomers is ~60/40, previously reported by Seifert *et al.*⁴ to be the equilibrium ratio for these isomers in crude oils. The second eluting isomer possesses the naturally occurring stereochemistry (22R). It was previously thought that crude oils with a 22R/22S ratio of >1 have never been observed since such a distribution would indicate lack of sufficient maturity for petroleum generation⁴.

We now report the first observation for Australian crude oils of a higher proportion of the C₃₁-22R diastereomer than the C₃₁-22S diastereomer. This unusual distribution has been observed in at least two oils from the Gippsland Basin, one from the Surat Basin and one from the Carnarvon Basin but is most pronounced in the Turrum 2 oil discussed in detail here. Thus from a total of ~40 oils examined, 10% had a higher concentration of C₃₁-22R epimer than the C₃₁-22S epimer and several others had a 1:1 ratio of the 22R and S isomers. Shi Ji-Yang *et al.*⁵ have recently reported a similar occurrence in one oil from China and Seifert *et al.*⁴ reported oils from one basin where the 17 α (H), 21 β H 22R:22S ratio was greater than the proposed equilibrium ratios and where ratios as low as 1.2 were observed in the least mature oils. However, the present study suggests that such a distribution is not uncommon in crudes from several Australian basins.

The most striking example of this unusual ratio was observed in an oil from the Turrum well in the Gippsland Basin for which the *m/z* 191 chromatogram is shown in Fig. 1b. In this example the ratio for 22S and R is 10/90 compared with the 60/40 predicted by Seifert *et al.*⁴ for mature oils, where the 22S and R isomers are supposedly in thermodynamic equilibrium. Furthermore, the ratio for the C₃₂-22S and R diastereomers is analogous to the C₃₁ ratio in that the 22R diastereomer is present in higher concentrations than the 22S diastereomer. Examination of complete spectra taken over the peak from the second eluting isomer showed no evidence for the presence of gammacerane which has been reported to co-elute with the C₃₁-22R-homohopane on non-polar columns⁵. Comparison of this oil with that taken from a reservoir 2,000 ft deeper in the same well illustrates a significant difference in distribution of the hopanes (Fig. 1c). The deeper oil has a more characteristic hopane distribution pattern dominated by the 17 α H, 21 β H-C₂₉ component and with the C₃₁-22S and R isomers present in a

53/47 ratio. It is generally thought, though not unequivocally proven, that the oils from this part of the basin have the same or very similar sources⁶. If this is the case for these two oils, what explanations are available for the unusual ratio of C₃₁-22S and R diastereomers in the shallower oil plus several other differences in individual hopane distributions?

The location of the Gippsland Basin and the onshore Victorian brown coal deposits prompted a re-examination of the triterpanes present in Yallourn lignite. The sample of Yallourn lignite used in this study was taken from the onshore area of the Gippsland Basin. Most of the offshore areas of the basins contain relatively high proportions of dispersed coaly material

Fig. 1 Partial single-ion chromatograms of *m/z* 191 for Kingfish (a) and Turrum (b, 5,177 ft; c, 7,624 ft) oils from the Gippsland Basin and an extract from Yallourn lignite (d). Samples were analysed on a Finnigan 4023 GC-MS system. GC conditions were: 40 m fused silica WCOT column programmed from 10 to 200 °C at 20 °C min⁻¹ and then 4 °C min⁻¹ to 280 °C. The mass spectrometer was operated in multiple-ion detection mode at an electron energy of 70 eV and ion current of 250 μ A. Peak identification: 1, 18 α (H)-22,29,30-trisnorhopane; 2, 17 α (H)-22,29,30-trisnorhopane; 3, 17 β (H)-22,29,30-trisnorhopane; 4, 17 α (H),21 β (H)-28,30-bisnorhopane; 5, 17 α (H),21 β (H)-30-norhopane; 6, 17 α (H),21 β (H)-hopane; 7 and 8, 22S and R 17 α (H),21 β (H)-30-homohopane; 9 and 10, 22S and R 17 α (H),21 β (H)-30,31 bishomohopane; 11, 17 β (H),21 β (H)-30-homohopane. Inset in b is $\times 10$ magnification.

that is very similar to the onshore lignite and brown coal deposits although of a slightly higher maturity. Figure 2a shows a cross-section through this part of the Gippsland Basin and illustrates the presence of non-marine sands, shales and coals in the reservoir areas of the Turrum well. Figure 2b shows the stratigraphical sequence through the Turrum 2 well, again indicating the presence of interspersed coals in the reservoir zones. In this study the Yallourn lignite is used as a concentrated example of the type of material that is typically dispersed throughout the basin.

Van Dorsselaer *et al.*⁷ found that the major triterpane component in Yallourn lignite is the $17\alpha(\text{H})$, $21\beta(\text{H})$ - $22\text{R}-\text{C}_{31}\text{H}_{54}$ homohopane diastereomer. The m/z 191 chromatogram (Fig. 1d) for the hydrocarbon fraction from a sample of Yallourn lignite demonstrates that in addition to the $17\alpha(\text{H})$, $21\beta(\text{H})$ - $22\text{R}-\text{C}_{31}$ -homohopane, $17\beta(\text{H})$ - C_{27} -trisorhopane and $17\beta(\text{H})$, $21\beta(\text{H})$ - C_{31} -homohopane were also present as very minor components. Note that this sample of lignite is only being used to demonstrate the unusual hopane distribution; it is unlikely that it is specifically responsible for the unusual hopane distributions in the shallow Turrum oil because it does not contain the C_{32} -homohopanes. Detailed analysis of the Turrum 2 oil showed that the two $17\beta(\text{H})$ -hopanes mentioned above were also present in the oil. The presence of $17\beta(\text{H})$ -hopanes in crude oils is in itself a very unusual observation. It is generally considered that at the maturity levels required for the formation of petroleum, the $17\beta(\text{H})$ isomers will be converted into their $17\alpha(\text{H})$ analogues, although trace amounts of the $17\beta\text{H}$ C_{27} -hopane are present in genuine source rocks and petroleum⁸. If this is the case, the only explanation for the presence of the two $17\beta(\text{H})$ hopanes plus the predominance of the $22\text{R}-\text{C}_{31}$ -homohopane seems to be that they are derived directly from an immature brown coal source, similar to the Yallourn lignite, which has been in contact with the oil.

There are alternative explanations for this unusual distribution of triterpanes. MacKenzie *et al.*^{9,10} have proposed that an oil can appear immature on the basis of one type of biological marker parameter but be apparently mature, or 'normal', in terms of another type of measurement. In other words, a measurement of the extent to which one reaction type has occurred will correspond to different values of a measurement based on a different reaction type. Determination of the % $20\text{S}/20\text{R} + 20\text{S}-24\text{-ethyl}-5\alpha(\text{H}), 14\alpha(\text{H})17\alpha(\text{H})$ -cholestane for the two Turrum oils from the m/z 217 chromatogram gives values of 23% and 43% for the shallow and deep oils, respectively. The value for the shallow oil is similar to that observed by Shi Ji-Yang *et al.*⁵ for samples of immature Chinese oils.

The immaturity of the Turrum 2 oil based on the % $20\text{S}-\text{C}_{29}$ -sterane combined with the hypothesis of Mackenzie *et al.*^{9,10} would suggest that the Turrum 2 oil is an immature oil similar to those first observed by them in samples from China. Whilst agreeing in general with their hypothesis, we feel that the Turrum 2 oil, and possibly other Australian oils are exceptions to this hypothesis. We propose that the unusual distribution of the 22R and $\text{S}-\text{C}_{31}$ -homohopanes in the Turrum 2 oil arises as a result of oil coming into contact with relatively immature brown coal zones in the reservoir areas. Many of the reservoirs in the Gippsland Basin contain significant quantities of dispersed coaly material (Fig. 2a, b) and hence the oil would be in contact with this material for a relatively long period of time. The strongest pieces of supportive evidence for this theory are the presence of the $17\beta(\text{H}), 21\alpha(\text{H})-\text{C}_{27}$ and C_{31} -hopanes in both the oil and a sample of onshore Yallourn lignite and the predominance of the $22\text{R}-\text{C}_{31}$ -homohopane in both the oil and the extract of the Yallourn lignite. The results of this study suggest that, in certain cases, the biological markers in crude oils may not always be derived directly from major source rocks but may be acquired during migration or after accumulation in the reservoir. Such an observation may be unique for Australian basins where the content of coal is generally much higher than for other oil-bearing basins around the world.

The representation of auditory space in the mammalian superior colliculus

A. R. Palmer & A. J. King

National Institute for Medical Research, The Ridgeway, Mill Hill, London NW7 1AA, UK

The superior colliculus (SC) is involved in orienting responses to sensory stimuli¹ and contains detailed sensory and motor maps¹⁻³. The visual and somatosensory maps have been well documented⁴⁻¹⁵ and are topographic representations of the primary receptor surfaces. However, the formation of an ordered map of auditory space is rather more problematic as it requires either reorganization of monaural information or combination of information from both ears^{16,17}. Nevertheless, such an ordered map has been demonstrated in the midbrain of the barn owl¹⁸ and there have been indications that a similar map occurs in mammals^{7-9,12,13,19-21}, although a recent study suggests that this is not the case in the cat²². Here we report briefly the results of our study, showing that auditory space is precisely represented in the deep layers of the guinea pig SC. This map of auditory space resembles the visual map in that cells responding to sounds in the anterior contralateral field are located rostrally, while those responding to sounds in the posterior contralateral field are located in caudal SC.

We have recorded auditory evoked responses of 155 cells throughout the deep layers of the guinea pig SC. After anaesthetizing the animals²³, the tracheae were cannulated and rectal temperature was maintained at 37 °C. A craniotomy was performed above the cortex overlying the SC and recordings were made with cortex intact using glass-coated tungsten microelectrodes. The animals were held from behind in a normal position with a minimal head-holder screwed to the skull. The pinnae, which were reflected by the initial incision, were carefully repositioned by sutures. The animal was placed at the centre of an anechoic chamber on a small table around which, level with the interaural plane at a radius of 1.1 m, was an array of loudspeakers at 22.5° intervals. A small flashing light was used to locate the centre of the visual receptive fields (RFs) of cells in the superficial layers. Electrodes were positioned to traverse the representation of the horizontal visual meridian so that auditory fields, if in register, would occur within the arc of speakers. A 100-ms burst of noise with a bandwidth of 100–20,000 Hz was presented repeatedly once every 1–2 s, while

Fig. 2 Surface view of the guinea pig SC showing the location of six electrode penetrations at successive positions along the rostro-caudal axis. Polar diagrams are shown for six SC cells recorded in the electrode penetrations indicated. Each graph shows only responses at one sound level, at which the field was well defined, near threshold for each cell. Bars indicate 0.5 spikes per stimulus. Stars indicate the position of the RF of superficial layer visual cells. The cell showing two lobes could not be allocated a single preferred sound location and does not appear on the subsequent figure.

the recording electrode was being advanced through the deep layers of the colliculus. Once a single cell was isolated, its average discharge was measured in response to sound from the 11 speakers. Electrolytic lesions were placed in each electrode track to enable accurate identification of the recording site from histological reconstructions.

Of the cells we have studied, 75% showed a preference for sound originating from a particular direction. The effect of stimulus intensity on this directional preference was examined

Fig. 1 Number of spikes evoked from a SC cell per presentation of a 100-ms wideband noise stimulus, as a function of the horizontal location of the sound source and its level. Each value plotted on the radial axis of the polar graph is the mean response to 32 presentations. The repetition rate of the stimulus was decreased until an optimal response was obtained which usually occurred at one presentation every 1–2 s. In *a* the repetition rate was one every 1,800 ms and in *b* one every 1,600 ms. Only spikes occurring during a time window 10–70 ms after the stimulus onset were counted to minimize the contribution of spontaneous discharges. The bar represents a radial extent equal to 0.5 counts per presentation. It is clear that the discharge rates measured are extremely low. Although habituation in the SC deep layers has been well documented, increase in the inter-stimulus interval beyond those used did not increase the discharge probability. Such poor responsiveness has been attributed by several authors to the use of inappropriate stimuli. For example, cells in deep SC are known to be more responsive to moving stimuli which were not possible with the present apparatus. The angle of the polar plot represents the angular horizontal position of the loudspeaker. The star symbol indicates the position of the centre of the visual RF of cells in the superficial layers encountered in the same electrode penetration. Note that the highest sound level did not evoke the biggest response. Such non-monotonic responses were frequently encountered.

Fig. 3 Four identical surface views of the guinea pig SC. *a* Shows the position of electrode penetrations in which visual responses in the superficial layers were observed, but no auditory responses could be detected in the deeper layers. *b-d* Show respectively the position of cells which showed a preference for sounds located at 0–45°, 67.5–90° and 112.5–157.5°.

in 92 cells. Of these, 39% were narrowly tuned to a particular direction regardless of the sound level used, whereas the directional tuning of the remaining 61% broadened markedly with increasing stimulus intensity. Two examples of cells showing these characteristics are illustrated in Fig. 1. The cell shown in Fig. 1*a* responded to sound emanating from a limited spatial angle in front of the animal, even when noise levels were more than 25 dB above its minimum threshold. Figure 1*b* shows the response of a cell which preferentially responded to sounds from a particular direction only for noise levels near threshold. For levels even a few dB above this, however, the range of effective sound locations expanded, particularly in the caudal direction, in some cases occupying the whole contralateral field. The only cells which were driven by sounds in the ipsilateral auditory field were those with preferred sound locations at or near 0° (see Fig. 1*a*). Of 54 penetrations in which auditory responses were observed, more than one cell was found in 40. Tuned cells in a single penetration responded optimally to sounds from the same direction.

As the site of the recording electrode was moved from the anterior to the posterior part of the superior colliculus, the location of sounds to which the cells responded most vigorously shifted from the anterior to the posterior auditory field of the animal. This spatial representation of auditory space is analogous to the visual map over the collicular surface. Figure 2 shows data from a single animal in which responses from six electrode positions were analysed. The cells at each electrode site attended to a narrow region of space and formed an ordered array including the entire hemifield. Whether the vertical axis is also represented in the medio-lateral axis of the colliculus remains to be investigated.

That cells in a particular region of the superior colliculus are tuned to a specific location can also be illustrated using pooled data from different animals. Figure 3 illustrates the collicular position of 117 cells which showed a preference for sound location, grouped according to spatial location of their auditory receptive fields. These data indicate a reasonably strict topographical mapping of the auditory projection onto the deep layers of the SC over most of its rostro-caudal dimension (pooling of data and other unavoidable inaccuracies obscures the monotonic progression shown in Fig. 2). We did not find any cells responsive to auditory stimulation in 15 penetrations through the rostral pole of the SC (as indicated in Fig. 3*a*) even though these tracks certainly traversed both deep and superficial layers (in which visual responses were recorded).

Having demonstrated a well organized auditory map in the SC an obvious question is whether this map is in register with those of other modalities. Certainly, the visual maps found in other rodents^{4,8–10,12–14} resemble the topographic arrangement shown in Fig. 3. More direct evidence is, however, provided by our own visual RF data. In each penetration we routinely determined the centre of the RFs of cells in the superficial layers. The positions of these were in register with the auditory

fields ($\pm 11^\circ$) in 43% of cases, but often severe discrepancies of up to 60° occurred, particularly for auditory fields in front or behind the animal. Three main factors contributed to this discrepancy: (1) the abnormal position of the eye due to anaesthesia (on average the eye was 10.5° forward and 22° downward of the central orbit position). (2) The rostral and caudal curvature of the SC caused sampling from different topographical regions in the superficial and deeper layers. (3) The absence of auditory responses in the rostral SC. Allowing for these it appears that when the eye is in a normal position the maps of visual and auditory space are in register. Registration has also been indicated by previous authors^{7–9,12,13,19–21}, but final resolution of this question awaits detailed simultaneous mapping of the different modalities.

It is generally accepted that the auditory system localizes sound by comparing time and intensity differences between the two ears, although significant monaural localization has been demonstrated¹⁷. As we have shown here, cells within the SC are sensitive to the cues associated with a specific spatial location and are arranged to produce an internal representation of these locations. We do not yet know either the cues used by the guinea pig in localizing sound or the developmental strategies used in ordering the neural connections. For these reasons directional hearing is and has been a particularly challenging research problem, the ultimate solution of which will depend on understanding the nature of the excitatory and inhibitory interactions between the two ears and the detailed circuitry of the auditory projections.

Metamorphosis of the insect nervous system: changes in morphology and synaptic interactions of identified neurones

Richard B. Levine* & James W. Truman

Department of Zoology, University of Washington, Seattle, Washington 98195, USA

The nervous system of holometabolous insects directs the behaviour of three radically different stages, the larva, pupa and adult. In some cases, larval neurones degenerate during metamorphosis and are replaced in the adult by neurones derived from retained embryonic neuroblasts^{1,2}, but many larval neurones are retained and undergo a morphological and synaptic reorganization which allows them to perform new functions in the adult^{3,4}. This cellular rearrangement, however, creates a problem in that the developing adults continue to display pupal-like behaviour even after the neurones attain their adult form. We show here that in the tobacco hornworm, *Manduca sexta*, the adult function of a neurone is prevented from being expressed precociously by the persistence of inhibitory influences that are removed abruptly at adult emergence.

We have investigated the changes that occur during metamorphosis in the relatively simple abdominal portion of *M. sexta*. During adult development several external muscle groups differentiate and are innervated by motoneurones whose larval targets have degenerated shortly after the larval-to-pupal molt⁴. The motoneurone MN-1 controls dorsal external oblique muscle DEO 2 in the larva, but loses this target in the pupal stage, innervating a new dorsal external muscle (DE 4) in the adult (Fig. 1). During this transition the cell undergoes considerable anatomical reorganization⁵. Figure 1 shows that the growth of new processes was most vigorous between days 4 and 12 of development and the adult morphology was essentially established by day 14.

The structural reorganization of MN-1 is correlated with changes in the pattern of synaptic inputs to the neurone. We chose to study a stretch receptor, specifically SR-3, which is located bilaterally in each abdominal segment and is present throughout the life of the insect⁵ (Fig. 1). Each sensory cell sends an axon into the central nervous system (CNS) and responds to stretch of its segment with a burst of action potentials⁶. Its central processes, which are similar at all stages, branch in the dorsal region of the neuropil and are confined totally to the hemiganglion in which they enter (Fig. 1).

During the larval stage we observed that MN-1 received excitatory input from the SR-3 ipsilateral to its axon and target muscle (Fig. 2). A single electrical stimulus to the stretch receptor resulted in a constant-latency excitatory postsynaptic potential (e.p.s.p.) in the motoneurone. After subtracting the portion of this latency due to conduction of the SR-3 spike into the CNS (obtained by recording from SR-3 in the periphery and within the CNS), the remaining latency was less than 1 ms, a delay consistent with the pathway being monosynaptic. The processes of both neurones extended through similar regions of the dorsal neuropil and simultaneous cobalt backfills revealed areas of potential contact. This pathway remained unchanged throughout metamorphosis.

The larval MN-1 was inhibited by the SR-3 contralateral to its target. Stretch of this SR-3 or trains of electrical stimuli to its axon caused inhibition of tonic MN-1 activity, which was associated with a hyperpolarization and a conductance increase in the motoneurone (Figs 2, 3). The inhibitory postsynaptic

potential (i.p.s.p.) evoked by a single spike in the contralateral SR-3 had a long, variable latency and decreased rapidly in an all-or-none fashion during repeated stimulation. The terminal branches of the contralateral SR-3 were anatomically separated from the main dendritic arborization of MN-1. The only point of possible contact between the two neurones—the neurite leading from the soma of MN-1—passed ventral to the processes of SR-3. These data suggest that the inhibitory influence of the contralateral SR-3 is mediated by a polysynaptic pathway.

In the early pupal stage (days 1 and 2 after pupal ecdysis), the contralateral SR-3 continued to inhibit MN-1, but the relationship changed dramatically during metamorphosis. In the adult moth (1–2 days post-emergence), trains of stimuli to the contralateral SR-3 evoked a large depolarization and firing of the motoneurone (Fig. 3). Single stimuli resulted in an e.p.s.p. with a short, constant latency (Fig. 2). The i.p.s.p. which resulted from stimulation of the same SR-3 in earlier stages was not revealed by hyperpolarization or depolarization of the adult MN-1. On reexamination of the pathway in the larva, it was found that hyperpolarization of MN-1 caused reversal of the i.p.s.p. in a single step, and failed to reveal a hidden, short latency excitatory component in the interaction (Fig. 2). This change in the functional relationship of SR-3 with MN-1 coincides with the morphological changes shown by the motoneurone. The proximity of the new adult-specific dendrites to the terminal branches of the contralateral SR-3, together with the short, constant latency of the new e.p.s.p., suggests that the SR-3 makes direct contacts with these new dendrites.

MN-1 attains its adult morphology and has full control of its new target 3–4 days before adult emergence. Despite these changes, however, the behaviour of the animal (which is covered by a pupal cuticle), is pupal in character until the time of adult emergence, when its behaviour abruptly switches to that of the adult⁷. Certain behaviours such as the defensive gin-trap reflex are unique to the pupal stage⁸, and new neuronal pathways must develop without disrupting them. On the last day of adult development, individual SR-3 impulses evoked a biphasic response in the contralateral MN-1, a short latency e.p.s.p. followed by an i.p.s.p. (Fig. 2). Occasionally the e.p.s.p. was sufficient to evoke an action potential in MN-1, but trains of stimuli or stretch of the receptor resulted in inhibition of the motoneurone (Fig. 3). The inhibitory component disappeared abruptly following adult emergence. Within 30 min of emergence, bursts of stimuli to the contralateral SR-3 evoked a pure excitatory response in MN-1 and single stimuli produced a short latency e.p.s.p., without an i.p.s.p. (Fig. 2). Furthermore, depolarization of the motoneurone revealed no i.p.s.p., and spontaneous activity was not inhibited during the period formerly associated with the i.p.s.p.

The functional and anatomical reorganization of MN-1 is reasonable in terms of its behavioural roles in the three stages of insect life. Both the larval and adult targets of MN-1 are near the dorsal midline of the abdominal segment. In the larva and pupa many behaviours depend on the ability of the abdomen to flex laterally. The right and left targets of MN-1 would be antagonists in this situation. Within a day after adult emergence, however, the abdomen of the moth becomes relatively rigid, and flexion is confined to the dorso-ventral plane. This lack of lateral movements makes asymmetric SR-3 inputs relatively pointless, as the only movements that are possible are ones for which the two DE 4 muscles must contract or relax together. Indeed, in the adult the right and left MN-1s often fire together in synchronous bursts. This synchrony is not due to direct coupling between the cells, which suggests that they share numerous common inputs.

A simple model for the change in the relationship of MN-1 to the contralateral SR-3 is shown in Fig. 3. In the larva, the contralateral SR-3 inhibits MN-1 through an unidentified interneurone. During adult development MN-1 grows new dendritic branches and accepts excitatory synapses from the contralateral SR-3. Before adult emergence, however, this excitatory connection is not behaviourally effective because the persisting parallel

*Present address: Department of Biology, Rice University, Houston, Texas 77001, USA.

Fig. 1 Structural reorganization of MN-1. *a*, Camera lucida drawings of MN-1 in the larval, early pupal and adult stages. Neurones were stained by passing positive current through an intracellular micropipette filled with 10% cobalt nitrate, and the stain enhanced in whole mount with a modification of the Timm's silver intensification procedure¹¹. In the larval and adult stages, MN-1 was identified by correlating activity recorded intracellularly from the motoneurone with that recorded extracellularly or intracellularly from the target muscle. In addition, action potentials in the MN-1 axon may be identified unambiguously in extracellular records from the third branch of the 'dorsal' segmental nerve, which allows MN-1 identification in the pupal stage. Note that during adult development MN-1 acquires a new dendritic field ipsilateral to its soma. *b*, Growth of the dendritic field ipsilateral to the MN-1 cell body. Neurones were stained at various times during adult development by back-diffusion of cobalt through the cut axon, followed by silver intensification of sectioned material. Although the period of adult development is 18 days, dendritic growth is essentially complete by day 14. *c*, Morphology of the stretch receptor (SR-3) sensory cell within the abdominal ganglion of an adult. The cell's morphology is similar throughout the animal's life. Note that its processes do not cross the midline of the ganglion. Although not shown, the processes of the sensory cell extend into the adjacent abdominal ganglia. *d*, Abdominal musculature in the larva and adult. In each case half of one abdominal segment is shown as though the animal had been cut along the dorsal midline and pinned open. The ventral nerve cord is on the left. The intersegmental muscles have been dissected away to reveal the external muscles, all of which die at the end of the larval stage and are replaced by newly generated muscles in the adult. The motoneurone MN-1 innervates a dorsal external oblique muscle (DEO 2) in the larva, and a dorsal external muscle (DE 4) in the adult. The right-hand stretch receptor (SR-3) is shown at each stage.

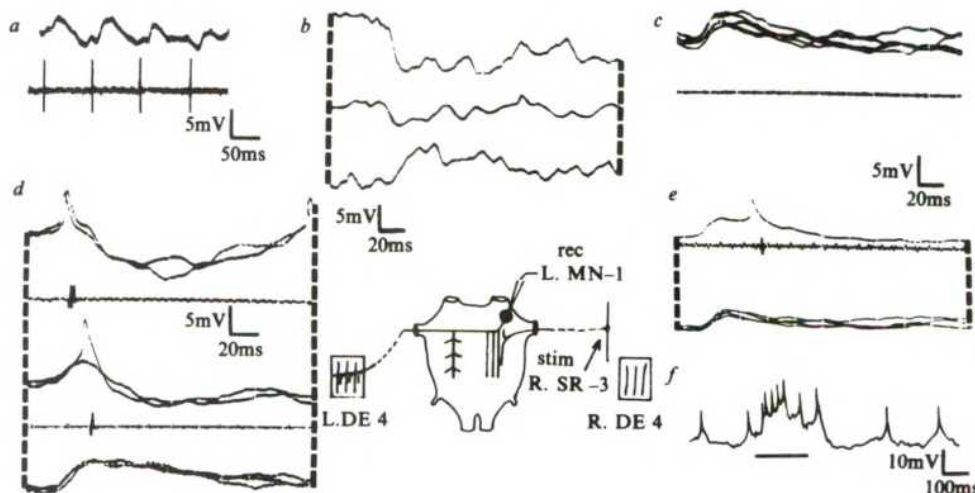

inhibitory pathway is always co-activated. An alternative interpretation is that the inhibitory synapse of the larval stage becomes excitatory and passes through a bifunctional stage⁹. Our data suggest, however, that the larval pathway is polysynaptic, while the adult pathway is direct.

The inactivation of the inhibitory pathway may be triggered

by eclosion hormone, which is released at the end of adult development and acts on the nervous system to release the emergence behaviours¹⁰. A second possible signal is the steroid 20-hydroxyecdysone, the reduction of which late in adult development triggers the death of many motoneurons and interneurons (J.W.T. and L. M. Schwartz, in preparation).

Fig. 2 Influence of SR-3 on MN-1 at different stages in the life cycle. *a*, The larval MN-1 is excited by the SR-3 ipsilateral to its target muscle. Each action potential in the SR-3 sensory cell (bottom, recorded near the sensory organ) causes an e.p.s.p. in the ipsilateral MN-1 (top). *b*, Inhibition of the larval MN-1 by the contralateral SR-3. A single electrical stimulus to the contralateral SR-3 (at the start of each trace) caused an i.p.s.p. in MN-1. The i.p.s.p. was enhanced by depolarization of MN-1 (top), and reversed by hyperpolarization (bottom). Note that a short-latency e.p.s.p. is not present (compare with *c-e*). *c*, Influence of the contralateral SR-3 on MN-1 in an adult 30 h after emergence. Intracellular (top), and extracellular (bottom) records from MN-1. Single stimuli to the SR-3 (at the start of the trace) evoked a constant-latency e.p.s.p. in the contralateral MN-1 (multiple trials, compare with *b*). *d*, Traces same as in *c*. About 5 h before adult emergence, single stimuli to SR-3 evoked a biphasic response in the contralateral MN-1. The later, inhibitory component was enhanced by depolarization of the motoneurone (top), and reversed by hyperpolarization (bottom). The early component may lead to an action potential (also visible in the extracellular records). *e*, Single stimuli to SR-3 30 min after emergence evoked only the short-latency depolarizing response in the contralateral MN-1 (bottom). Depolarization of the motoneurone revealed no inhibitory component (top). Note that action potentials were not blocked during the period formerly associated with the i.p.s.p. *f*, Bursts of stimuli to the contralateral SR-3 (bar) 30 min after emergence excited the MN-1. The insert shows the experimental set-up for *b-e*. The adult morphology of MN-1 is drawn schematically. rec, Recording electrode; stim, stimulating electrode.

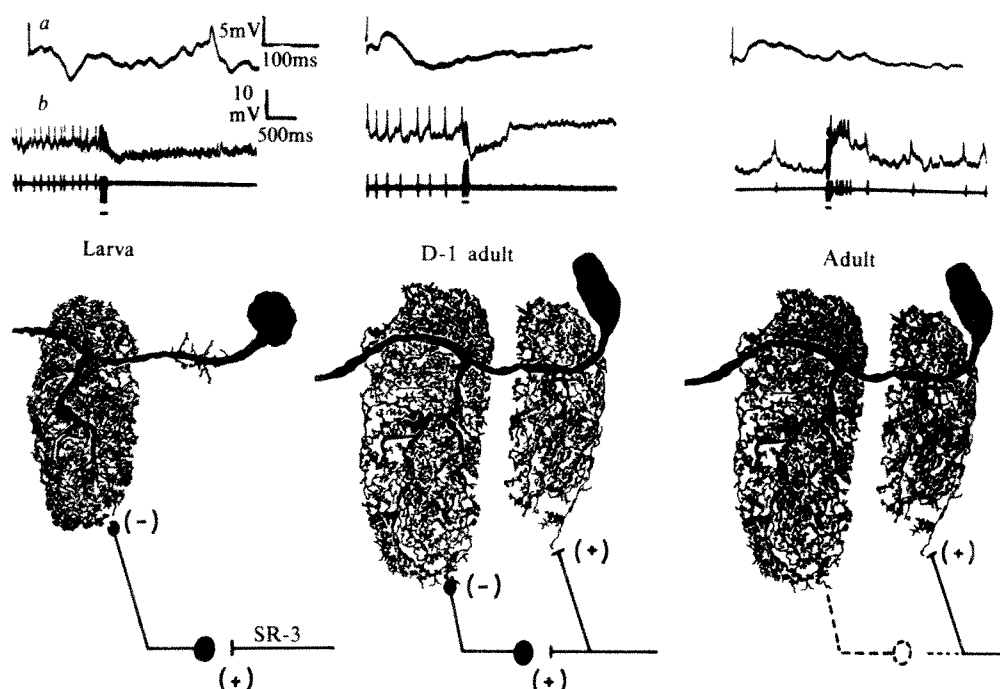

Fig. 3 Model for the changes observed in the interaction between MN-1 and SR-3. *a*, Response of MN-1 to single stimuli delivered to the contralateral SR-3. *b*, Response of MN-1 to a burst of stimuli (100 Hz) to the contralateral SR-3, which mimics the response of the receptor to natural stretch. Intracellular (top) and extracellular (bottom) records from MN-1. In the larva MN-1 is inhibited by the contralateral SR-3 through a polysynaptic pathway. The processes of SR-3 do not cross the midline of the ganglion, and lie in a different region of neuropil from the main neurite of MN-1. Single stimuli evoked long-latency i.p.s.p.s. On the day before adult emergence (D-1 adult) SR-3 evoked a biphasic response in the contralateral MN-1; the original inhibitory path was co-activated with a new direct excitatory path. Bursts of receptor spikes, however, still inhibited MN-1. The new dendritic processes of MN-1 overlapped with those of SR-3. After adult emergence, the inhibitory component was lost, and the SR-3 evoked a pure depolarizing response in the contralateral MN-1.

The inhibitory interaction between SR-3 and MN-1 is permanently inactivated after adult emergence. However, a reversible inactivation of parallel inhibition might be applicable to other situations in which hormones or other factors alter markedly the function of a particular neural pathway.

A transient outward current in a mammalian central neurone blocked by 4-aminopyridine

B. Gustafsson*, M. Galvan†, P. Grafe† & H. Wigström*

It is becoming increasingly clear that nerve cells in the mammalian central nervous system (CNS) have a very complex electroresponsiveness. They exhibit not only time- and voltage-dependent Na^+ and K^+ conductances, analogous to those in the squid giant axon¹, but also a variety of other conductances that have a significant role in the control of cell excitability. Of the outward currents, there are, in addition to the delayed rectifier, the Ca^{2+} -activated K^+ current^{2,3} which underlies the long-lasting spike afterhyperpolarization, and the M current⁴, a non-inactivating K^+ current evoked by membrane depolarization and blocked by muscarinic, cholinergic agonists. We demonstrate here the existence in a mammalian central neurone (hippocampal CA3 pyramidal cells) of yet another outward current, which is transient and may be carried by K^+ ions. Further, the experiments show that this current is substantially reduced by the convulsant 4-aminopyridine (4-AP)⁵, resulting in a marked increase in cell excitability.

The experiments were performed on transverse slices (400–600 μm thick) of guinea pig hippocampus. The slices were kept either half or totally immersed (see below) in an experimental chamber perfused with a solution containing (in mM): NaCl, 123; KCl, 3.0; CaCl_2 , 2.0; MgSO_4 , 2.0; NaHCO_3 , 26; glucose, 10. The temperature was kept constant at either 33 °C or 26 °C. Neurones in the CA3 region were impaled with 3 M KCl-filled microelectrodes and voltage-clamped using a single electrode switched clamp circuit (a DAGAN 8100 or a custom-built amplifier of similar design⁶); the switching frequency was 3 kHz and the duty cycle was 10–25%. Possible artefacts involved in the use of these instruments have been discussed elsewhere⁷. Drugs were applied in fixed concentrations to the bathing solution and the data collected were either computer-averaged or photographed from the oscilloscope screen using Polaroid film.

Figure 1a illustrates that in control solution, constant-current pulses applied to CA3 neurones at a resting potential of -70 mV evoked electrotonic potentials (ETPs) which were smaller in the depolarizing than in the hyperpolarizing direction. Closer examination of these depolarizing ETPs shows that they increased rapidly, then suddenly levelled off in a manner which suggests that an opposing outward current had been activated. This behaviour was more clearly seen when Na^+ and Ca^{2+} action potentials were blocked by addition of tetrodotoxin (TTX) and Mn^{2+} ions (Fig. 1b). A similar outward-going rectification (albeit at more depolarized membrane potentials) has been observed in sympathetic and hippocampal CA1 neurones and attributed to depolarization-activation of M channels^{4,8,9}. However, addition of muscarine in sufficient concentrations to block M channels, did not noticeably affect the observed outward rectification (Fig. 1c). Thus it seems that, in these

Fig. 1 Recordings of electrotonic potentials (ETPs) in CA3 neurones at 26°C. *a*, Control solution; *b*, in solution containing 3 μ M TTX and 4 mM $MnCl_2$; *c*, in solution containing 1 μ M TTX and 25 μ M muscarine chloride. (Slices were kept totally immersed in the solutions.) The membrane potential was set at -70 mV by passing steady d.c. current through the recording microelectrode, and the amplifier was set in the switched (sample-and-hold) current clamp mode. The top traces show rectangular constant current pulses and the lower traces the resulting membrane potential deflections. *a* and *b* were recorded from the same cell and illustrate the marked attenuation of the amplitude of depolarizing ETPs. Note the slow depolarizing 'creep' of the second largest depolarizing ETP leading to an action potential towards the end of the pulse. This creep was also often observed in the presence of inward current blockers. As judged from the amplitude of the smallest depolarizing and hyperpolarizing pulses, membrane resistance increased in the TTX-Mn solution, possibly due to blockade of tonic synaptic activity. *c* was recorded from another neurone and illustrates that the outward rectification was still present after blockade of possible M-currents by muscarine (Musc).

neurones, there is an outward rectifying current operating in the threshold range, that is distinct from M-channel activation.

Figure 2 shows voltage-clamp recordings from a CA3 neurone in a solution containing TTX. From a holding potential of -70 mV (Fig. 2*a*), hyperpolarizing voltages elicited small inward currents, which were relatively linear and time independent. When the cell was depolarized to potentials greater than -60 mV, a rapidly activating outward current was observed, which decayed over the next several hundred milliseconds. The peak amplitude of this transient outward current was increased as the cell was stepped to more positive potentials. This current-

voltage relationship is plotted in Fig. 2*c* (closed circles); it is nonlinear, indicative of voltage-dependent activation. It was also observed that the current amplitude varied with the holding potential, increasing with membrane hyperpolarization (-70 to -100 mV) and decreasing to zero at holding potentials more positive than -55 mV. Thus, when the same cell was held at -40 mV and subjected to step hyperpolarizations, only steps to potentials more negative than -55 mV were followed, on return to the holding potential, by a transient outward current (Fig. 2*b*). The relationship between the hyperpolarizing step and the resulting outward current is shown in Fig. 2*c* (open circles) and is an approximate measure of the inactivation characteristic of this current.

The transient outward current was observed in all CA3 neurones examined ($n = 35$), and had an amplitude of 4.2 ± 1.5 (\pm s.d.) nA ($n = 9$) as measured 30 ms following a 50–55 mV, 1–1.5 s hyperpolarizing voltage step from -30 mV, and back again. The activation kinetics were too rapid to be resolved using the single electrode clamp technique; our data show only that the current appears to have peaked within 10–15 ms. The inactivation consisted of an initial rapid phase followed by a very slow second phase, which lasted for up to several seconds (Fig. 2*b*); this form of decay could not be described by first-order kinetics.

A transient current having these characteristics has been described in invertebrate^{10,11} and vertebrate¹² neurones and has been shown to be mainly carried by K^+ ions. In the present experiments, an increase in the external K^+ ion concentration (40–60 mM with totally immersed slices) always decreased or abolished the transient outward current. A clear reversal was not obtained but this may simply reflect poor diffusion of K^+ ions into the slice, resulting in only a small positive shift of the K^+ reversal potential. Outward rectification, probably caused by activation of the transient outward current, persisted in solutions containing Ca^{2+} -channel blockers (Mn^{2+} ions) (Fig. 1*b*). Under voltage-clamp, it was also observed that the current was not blocked by Mn^{2+} , although the activation-voltage curve seemed to be shifted ~ 10 mV in the positive direction. This is, to a lesser extent, evident also from Fig. 1*b*. Thus, the results demonstrate the presence of a transient outward current in CA3 neurones, which induces a marked rectification in the current-voltage relation at membrane potentials close to threshold. This current is probably a K^+ -current that is not dependent on Ca^{2+} ion movements.

It has been shown previously that the convulsant agent 4-AP can (at mM concentrations) selectively reduce the amplitude of transient outward currents in invertebrate neurones¹³ as well

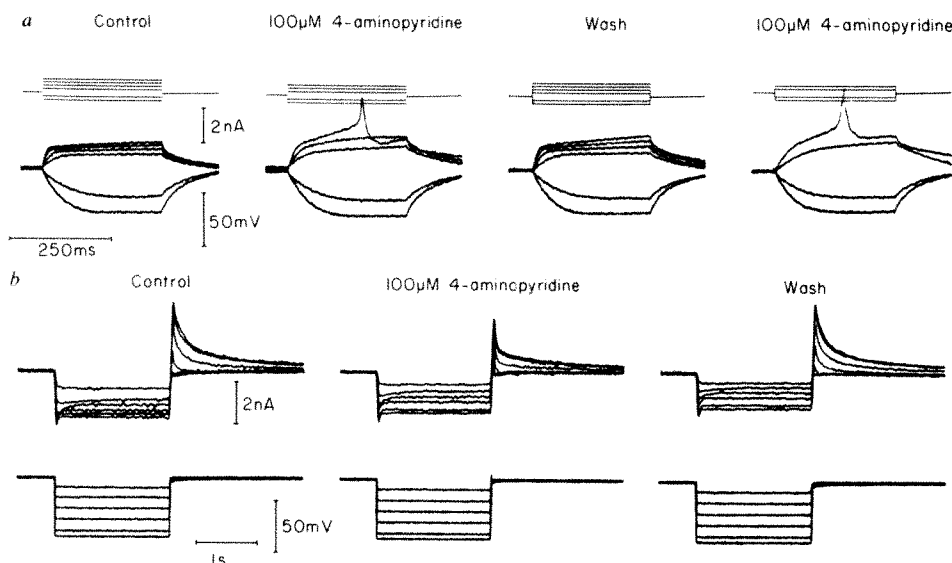

Fig. 2 Computer-averaged recordings of membrane voltage (upper traces) and current (lower traces) from a single CA3 neurone held at -70 mV (*a*) and -40 mV (*b*). Temperature, 33°C. Slices were kept half-immersed in the solutions. Transient outward currents were elicited by step depolarizations from -70 mV or following hyperpolarizations from -40 mV. Note that for large pulses, the membrane voltage attained initially deviated from the command level. This results from inadequate feedback gain—a consequence of single electrode clamping with relatively high resistance microelectrodes. In *b*, small inward current relaxations can be observed during small hyperpolarizing commands, suggesting the presence of M-current. Measurements of membrane voltage and current, made at the times indicated by the arrows in *a* and *b*, respectively, are plotted in *c*. ●, The current-voltage curve from -70 mV; ○, the relationship between hyperpolarizing command potential and the resulting post-pulse current.

Fig. 3 Effect of 4-AP on electrotonic potentials (*a*) and transient outward currents (*b*) measured in two separate CA3 neurones. The experiment illustrated in *a* (26 °C) was performed in the presence of 1 μ M TTX and 25 μ M muscarine chloride; *b* (33 °C) was performed in 0.5 μ M TTX. The slices in *a* were kept totally immersed, while those in *b* were kept half-immersed. In *a* the membrane potential was manually set at -70 mV; in *b* the holding potential was -30 mV. The current clamp records in *a* show electrotonic potentials before, at the end of and 60 min after bath application (8 min) of 100 μ M 4-AP. After a substantial recovery had been obtained, 4-AP was applied again for a longer period (20 min). Note that a maximum effect was not achieved during the first application, as evidenced by the much larger change from outward rectification resulting from the second, longer application. The amplitude of hyperpolarizing ETPs was almost unaltered by 4-AP as was the current necessary to hold the membrane at -70 mV. In *b*, the voltage clamp records illustrate that a brief (5 min) application of 100 μ M 4-AP substantially and reversibly reduced transient outward currents.

as in mammalian cardiac muscle fibres¹⁴. Figure 3*a* demonstrates that in CA3 pyramidal cells, 100 μ M 4-AP can reversibly reduce the outward rectification, resulting in a considerable increase in cell excitability; evidence for this comes from the appearance of a Ca^{2+} action potential. Furthermore, Fig. 3*b* shows that in voltage-clamp, the transient outward current was substantially blocked by 4-AP. These effects were evident after only a few minutes of 4-AP application at times when it was unlikely that the 4-AP concentration equalled that in the bathing solution. The classical K^+ -channel blocker tetraethylammonium chloride (TEA), which blocks delayed rectifier channels¹⁵ and Ca^{2+} -activated K^+ channels in vertebrate neurones¹⁶, did not (at 3 mM) have any significant effect on this current. Note, however, that even in the presence of high concentrations (500 μ M) of 4-AP (in which no transient outward currents were observed), some outward rectification from -70 mV remained. This may be related to the presence of M currents, which were also observed in these cells.

Thus, hippocampal CA3 pyramidal cells exhibit a transient outward current distinct from the delayed rectifier K^+ current, the Ca^{2+} -activated K^+ current and the M current. The activation-inactivation characteristics as well as the pharmacology are similar, in principle, to those of the so-called A current in invertebrate neurones and it seems reasonable to extend this terminology to mammalian central neurones. We cannot, however, be certain that the current described here is similar in all respects to that of invertebrates. Connor and Stevens¹⁷ proposed that the A current controls repetitive firing in gastropod neurones. Its long duration and large amplitude in CA3 neurones also suggest that A currents in these cells, together with the Ca^{2+} -activated K^+ conductance, could serve such a role. More importantly, our data show that A currents are capable of controlling the approach of membrane potential to spike threshold and thus contribute to the control of cell excitability. The activation kinetics suggest that A currents may even affect the action potential (see ref. 18) and excitatory postsynaptic potential trajectories. The postsynaptic excitatory effect of 4-AP can probably be explained by blockade of A currents, although other contributory mechanisms cannot yet be excluded¹⁹. The presence of such currents also in vertebrate nerve terminals might explain the facilitatory actions of aminopyridines on neurotransmitter release¹⁹. Nevertheless, it certainly seems that the postsynaptic effects of 4-AP may contribute to its convulsant action.

Serotonergic denervation partially protects rat striatum from kainic acid toxicity

Michael Berger, Günther Sperk & Oleh Hornykiewicz

Institute of Biochemical Pharmacology, University of Vienna, Borschkegasse 8a, A-1090 Vienna, Austria

We report here observations indicating that the rat striatum can be partially protected from the neurotoxic action of locally applied kainic acid (KA, a rigid structural analogue of glutamic acid¹) by procedures resulting in reduced serotonergic brain activity. This observation may be important because the striatal damage produced by KA shows morphological and neurochemical similarities to the changes seen in the striata of patients dying of Huntington's chorea^{2,3}, an hereditary brain disorder, and because functional and morphological brain changes induced by KA have been proposed as a close model for human epilepsy⁴. Our observations thus suggest that serotonergic brain mechanisms influence the development of neuropathological changes accompanying certain neurological disorders.

Half-maximal lesion of the striatum (with respect to marker enzymes for acetylcholine and γ -aminobutyric acid neurones, see Fig. 1*b*; for enzyme assays, see Fig. 1 legend) was reproducibly obtained by applying stereotactically (David Kopf apparatus) 2 nmol of KA dissolved in 1 μ l 0.9% buffered saline into the rostral part of the striatum (coordinates A: 7.9, L: 2.5, D: 0.9, according to the rat brain atlas of König and Klippel¹⁵) at a rate of 0.33 μ l min⁻¹. For all experiments male albino rats (Sprague-Dawley; Versuchstierzuchtanstalt Himberg, Austria) weighing 250–350 g were used. For stereotaxic operations the animals were anaesthetized with 50 mg per kg intraperitoneal (i.p.) pentobarbital; intracisternal (i.c.) injections were performed under ether anaesthesia.

The experimental results are expressed as percentage of enzyme activity related to the contralateral striatum (into which no KA was injected). This strategy seemed justified as the various drug pretreatments, which always affected both striata, had no statistically significant effect on the absolute enzyme activities, and the striatal KA-induced lesion did not influence the enzyme levels in the contralateral striatum. The use of each animal as its own control permitted the detection of even small drug effects on the KA-induced changes. In this respect, direct comparison between the means of absolute enzyme activities of the different groups yielded identical results; however, due to inter-individual variation, the degree of statistical significance between the groups was, as expected, correspondingly smaller.

As shown in Fig. 1*a*, administration of 200 μ g 5,7-dihydroxytryptamine (5,7-DHT) into the cisterna magna (i.c.)⁶ 10 days before intrastriatal microinjection of 2 nmol KA, reduced the effect of KA on the activity of the striatal marker enzymes glutamic acid decarboxylase (GAD) and choline acetyltransferase (CAT). The difference between the group of animals receiving KA alone and that pretreated with 5,7-DHT was statistically significant at the 0.1 per cent level (Student's *t*-test). The striatal serotonin level in the 5,7-DHT-injected animals was reduced to 40% of control value.

The same degree of protection of the striatum from KA toxicity as that attained by 5,7-DHT, could be achieved

Table 1 Effect of manipulations influencing brain serotonin on striatum lesioned with 2 mol kainic acid (injected intrastrially)

	% CAT \pm s.e.m.	(n)	% GAD \pm s.e.m.	(n)
5, 7-DHT i.c. + KA	68.9 \pm 2.4	(14)*	79.3 \pm 3.7	(14)*
KA	54.7 \pm 1.7	(15)	59.0 \pm 2.0	(15)
<i>p</i> -Cl-Phe i.p. + KA	74.0 \pm 6.4	(4)†	79.9 \pm 5.1	(4)†
KA	57.0 \pm 4.0	(6)	59.8 \pm 4.4	(6)
Metergoline i.p.				
+ KA	70.4 \pm 1.9	(6)†	70.6 \pm 2.6	(6)†
Solvent + KA	59.1 \pm 3.6	(7)	58.7 \pm 4.4	(7)
5,7-DHT i.str.				
+ KA	71.4 \pm 3.2	(8)†	73.9 \pm 4.0	(7)†
Saline + KA	62.0 \pm 2.6	(7)	59.0 \pm 4.5	(7)
Pargyline + 5-OH-Trp i.p. + KA	62.3 \pm 3.9	(15)	65.0 \pm 2.9	(15)
KA	57.3 \pm 2.7	(12)	58.2 \pm 3.0	(12)
5-MDMT + KA	58.2 \pm 5.9	(7)	65.3 \pm 5.0	(7)
KA	61.1 \pm 3.4	(8)	62.8 \pm 3.4	(8)

5,7-Dihydroxytryptamine (5,7-DHT) was administered intracisternally (i.c.) or intrastrially (i.str.) in N₂-bubbled 0.9% NaCl containing 0.05% ascorbic acid, 10 days before kainic acid (KA); the rats were pretreated with desipramine (25 mg per kg, i.p.), controls to i.str. 5,7-DHT injections received i.str. saline. *p*-Chlorophenylalanine (*p*-Cl-Phe; 300 mg per kg, in saline) was injected i.p. 6 days before KA. Metergoline (12 mg per kg) was dissolved in 5% polysorbate 80 and injected i.p. 1 h before KA; controls received 5% polysorbate 80 i.p. Pargyline (25 mg per kg, in saline) and L-5-hydroxytryptophan (5-OH-Trp; 5 mg per kg, in saline neutralized with acetic acid) were injected i.p. 30 and 15 min, respectively, before KA, and 5-methoxy-*N,N*-dimethyltryptamine (5-MDMT; 3 mg per kg, in saline) 15 min before KA. Only animals showing typical 'serotonin related symptoms'¹⁸ (especially 'wet dog shakes') were used for KA injection. Values are means \pm s.e.m., expressed as percentage of enzyme activity related to the contralateral non-injected striatum. Ranges of enzyme activities in the contralateral striata were for CAT, 24–38 nmol ¹⁴C-acetylcholine and for GAD, 11–16 nmol ¹⁴CO₂ formed per and mg wet tissue weight. Significance of the difference between corresponding groups was calculated using Student's *t*-test. Number of animals is given in parentheses.

* *P* < 0.001; † *P* < 0.05 compared with controls.

Fig. 1 Protective effect of i.c. injections of 5,7-dihydroxytryptamine (5,7-DHT) against the striatal toxicity of 2 nmol kainic acid (KA) (*a*), compared with the dose dependency of striatal KA-induced lesions (*b*). Activities of the striatal marker enzymes, measured 7 days after KA injection, are indicated on the ordinate as percentage of the contralateral non-injected striatum (means \pm s.e.m.). Glutamic acid decarboxylase (GAD) was assayed by trapping ¹⁴CO₂ formed from radiolabelled glutamic acid following the procedure of Miller *et al.*¹⁹. L-[1-¹⁴C]glutamic acid (4 nM), 0.5 mM pyridoxal phosphate and 1 h incubation at 37 °C were used. Choline acetyltransferase (CAT) was assayed by the Fonnum method²⁰ using [1-¹⁴C]acetyl-CoA (0.2 mM), 8 mM choline chloride, 0.1 mM physostigmine and 30 min incubation at 37 °C. ¹⁴C-acetylcholine was extracted with heptanone (3) containing 1% Na-tetraphenylborate. In the 5,7-DHT-treated rats striatal levels of serotonin were reduced by 60%, whereas dopamine levels remained unchanged, as determined by HPLC with electrochemical detection^{15,21}.

by i.p. pretreatment with *p*-chlorophenylalanine (*p*-Cl-Phe, 300 mg per kg), a serotonin-depleting agent⁷, or metergoline (12 mg per kg), a serotonin receptor blocker⁸ (Table 1). Although the protective effect of these drugs was of the same magnitude as that of 5,7-DHT, the statistical significance of the achieved differences was lower (0.02 < *P* < 0.05). However, taken together, these results strengthen the conclusion that the protective effect of i.c. 5,7-DHT against the striatal toxicity of KA was based on a reduction of serotonin levels in the brain.

Because 5,7-DHT given i.c. reduced not only the striatal serotonin but also the serotonin in the thalamus (–75%) and frontal cortex (–90%) (both brain regions are major sources of striatal input neurones), we tested the striatal specificity of the protective effect of 5,7-DHT. Thus, in a separate experiment, injection of 5 μ g 5,7-DHT (dissolved in 1 μ l 0.9% saline) bilaterally into the medial part of the striatum (coordinates⁵ A: 6.8, L: 3.6, V: 0.2) reduced the striatal serotonin levels by 65% whereas those in the frontal cortex were reduced by only 35%, with the thalamic serotonin remaining unchanged. Dopamine levels in the striatum were moderately reduced (–35%). The intrastriatal 5,7-DHT pretreatment, similar to the i.c. application, again afforded the same degree of protection against striatal KA toxicity, as judged by striatal GAD and CAT activities (Table 1). This indicates that the serotonergic system of the striatum itself was involved in the observed 5,7-DHT effect.

On the other hand, we have been unable to render intrastriatal KA more neurotoxic by i.p. pretreatment of the rat with pargyline plus 5-hydroxytryptophan (5-OH-Trp) or 5-methoxy-*N,N*-dimethyltryptamine (5-MDMT, Table 1), although both procedures can be expected to increase brain serotonin activity. This suggests that serotonin may influence

KA toxicity indirectly, especially as the correlation between kainate-induced neuronal degeneration and 5,7-DHT-induced striatal serotonin depletion was only moderately significant ($r = 0.50$ with 20 degrees of freedom, $0.02 < P < 0.05$).

In search of an explanation for our results, it is interesting that iontophoretically applied serotonin is generally assumed to exert an inhibitory influence on striatal neurone activity⁹⁻¹¹. Cortical ablation, which interrupts the excitatory glutamatergic input to the striatum, results in a dramatic reduction of striatal KA toxicity¹², so that we cannot exclude the possibility that deafferentation of the striatum as such may exert some protective effect, regardless of whether the transmitter involved is excitatory (as the cortico-striatal glutamatergic input is supposed to be) or not. However, in contrast to iontophoretically applied serotonin, the synaptically released amine may indeed have a net excitatory effect on striatal neurones. This is indicated by observations showing that lesion of the raphe-striatal serotonin pathway results in a substantial reduction of acetylcholine turnover in the striatum¹³. In fact, our present results, seen in conjunction with the effect of interruption of the glutamatergic cortical input to the striatum, may be taken

as indirect support for an excitatory role of striatal serotonin. Regardless of the nature of the neurophysiological effect of striatal serotonin, our results strengthen the notion that KA, in addition to its direct excitotoxic activity, triggers circuits of neuronal hyperactivity including the area injected and some particular afferents as essential components¹⁴. The dramatic rise in striatal serotonin (and dopamine) turnover observed after local injection of KA^{15,16} could reflect the involvement of these afferents in KA-elicited hyperactivity circuits. In this respect, it may be noteworthy that in Huntington's disease the severe loss of the intrinsic and output neurones population of the affected striatum results in a relative predominance of striatal input systems including those containing serotonin and dopamine¹⁷. It would be interesting to know if this relative and progressive predominance of striatal serotonin and dopamine exerts any detrimental influence on the time course of the morphological and functional deterioration of the Huntington striatum.

The nonapeptide bradykinin (Arg-Pro-Gly-Phe-Ser-Pro-Phe-Arg) and the decapeptide kallidin (Lys-bradykinin) are released during tissue damage and cause vasodilation, increased vascular permeability, altered gut motility and pain¹⁻⁴. Accordingly, they have been implicated in several pathological processes, including carcinoid tumours and postgastrectomy dumping syndrome. Symptoms of these two syndromes include flushing, light-headedness, headaches and diarrhoea⁵⁻⁹. Increased blood levels of bradykinin^{5,7-9} and kallikrein⁹, the bradykinin-releasing enzyme, have been noted in such patients and may explain these symptoms. However, while kinin-forming and -destroying activity has been noted in the gut¹⁰⁻¹⁴, bradykinin itself has not been directly demonstrated. Moreover, while bradykinin influences gut motility and electrical activity^{15,25,26}, most clinical diarrhoea is due to ion and fluid secretion into the gut lumen rather than altered motility¹⁶. We describe here specific bradykinin receptors in intestinal mucosa and muscle. We also report that bradykinin and several peptide analogues potently stimulate chloride secretion in the gut with a peptide specificity indicative of specific receptor interactions. These findings suggest a physiological and a pathological role for kinins in intestinal function. Throughout this report the term kinin will indicate both bradykinin and kallidin activities since in several cases the true active form is unknown.

Previously, we demonstrated specific ³H-bradykinin receptor-binding sites in guinea pig ileum¹⁷. The potencies of peptides at these binding sites correlated with their potencies in contracting smooth muscle, suggesting that the binding sites might be localized to muscle. The results shown in Table 1 demonstrate that specific bradykinin receptor-binding sites occur in the mucosa as well as in the muscle area. The relative potencies of bradykinin and six analogues listed in Table 1 are quite similar in both mucosa and muscle and correspond well with those observed previously in the total ileal tissue¹⁷. The 25-fold-enhanced potencies of the peptides observed in this study, compared to our earlier work, are due to enhanced specific activity and diminished degradation of the ³H-bradykinin. The relative potencies of bradykinin and its analogues at the ³H-bradykinin receptor-binding site closely parallels their potency in stimulating active chloride secretion. Removal of the arginine in the 9 position, forming Des-Arg⁹-bradykinin, destroys receptor-binding affinity and eliminates biological activity. Replacement of proline in position 3 with α -aminoisobutyric acid (AIB), forming AIB³-bradykinin reduces receptor-binding potency markedly in parallel with a decrease in biological activity. In contrast to internal changes in the bradykinin structure, addition of lysine to the amino-terminal only reduces the receptor-binding and secretory activity slightly. While Met-Lys-bradykinin is 30-50% as potent as bradykinin in affecting short-circuit current, it is only 10% as potent at ³H-bradykinin receptor-binding sites. It is possible that in the short-circuit current assay, Met-Lys-bradykinin is metabolized to the more potent Lys-bradykinin while conditions of the binding assay retard such metabolism (see Table 1 legend).

The localization of bradykinin receptors to both the mucosa and muscle layers of the ileum was confirmed by light microscopic autoradiographic studies (Fig. 1). Autoradiographic grains were apparent in highest density over the lamina propria surrounding both villus and crypt epithelial cells. Grains were also concentrated over the circular and longitudinal muscle layers. By contrast, grain density was sparse or absent over lymphatic tissue, as well as the myenteric ganglia. Inclusion of 1 μ M unlabelled bradykinin in incubations greatly reduced

* To whom correspondence should be addressed.

Fig. 1 Autoradiographic localization of ^3H -bradykinin (BK) receptor binding in guinea pig ileum. The dark-field photomicrograph (a) shows the autoradiographic grain distribution over the same tissue as the bright-field photomicrograph (b). Note that grains are concentrated over muscle layers (*) and also over the villi (between double arrows). Grains are almost entirely localized over the centre or lamina propria of the villi and are sparse or absent over the luminal surface of the epithelium. Grains are also absent inside the crypts of Lieberkuhn (single arrows) but are concentrated over the serosal side of the crypt epithelial cells. The dark-field photomicrograph (c) shows the absence of specific receptor binding in an adjacent 10- μM section when 1 μM unlabelled BK was included in the incubation buffer. The coverslip method of Young and Kuhar³³ was used. Guinea pigs were perfused through the heart with 500 ml of 0.1% formaldehyde in a mixture of equal parts of phosphate-buffered saline and 20% sucrose, pH 7.4. The ilea were then removed, embedded in homogenized calf cerebral cortex and flash-frozen in liquid nitrogen. Sections (10 μm thick) were cut in a cryostat at -12°C , thaw-mounted onto chrome alum gelatin subbed microscope slides and stored frozen at -20°C . Slides were warmed to room temperature, then incubated for 120 min at 4°C in medium containing 25 mM trimethylaminoethanesulphonic acid (TES) pH 6.8, 1 μM 1,10-phenanthroline, 0.2% bovine serum albumin (BSA) (protease-free), 1 mM dithiothreitol, 0.1 mM bacitracin, 1 μM captopril (SQ 14,225), 300 mM sucrose, and 0.2 nM ^3H -BK (52 Ci mmol⁻¹). Blanks were incubated in the same medium with the addition of 1 μM unlabelled BK. After incubation tissue sections were washed in 25 mM TES pH 6.8, and 1 mM 1,10-phenanthroline for 60 min (2×30 min) at 4°C . Sections were then dried rapidly in cold, dry air, NTB-2 emulsion-coated coverslips were apposed and the sections were exposed to the emulsion for 1 month.

grain density with the remaining grains being distributed diffusely. The pharmacological specificity was also indicated by biochemical experiments using the six bradykinin analogues listed in Table 1 and slide-mounted tissue sections. After incubation and washing, the tissue section was wiped off the slide with a circle of filter paper and the bound radioactivity assessed

by scintillation counting. In these experiments the affinity of bradykinin receptors was the same as in homogenate estimations. Also, ^3H -bradykinin binding is displaced by peptides with the same potencies as in homogenate experiments.

Bradykinin receptors in the muscle layers presumably mediate the contractile effects of bradykinin. To investigate the

Table 1 Relative potencies of bradykinin (BK) and several related peptides in receptor binding and short-circuit current assays

Kinin	Structure	Stimulation of short-circuit current EC ₅₀ (nM)	Inhibition of ^3H -BK binding

Des-Arg ⁹ -BK		No response	>10 ⁻⁶	>10 ⁻⁶

^3H -BK was prepared (by NEN) by reduction of 2,3-dehydroproline-BK with tritium gas, resulting in a specific activity of either 27 or 52 Ci mmol⁻¹. The radiochemical purity of the ligand was determined by HPLC both before and after binding assay. The HPLC system used separates all partial sequence fragments of BK including BK₂₋₉, BK₁₋₈ and BK₁₋₇. A μ Bondapak C₁₈ (Waters Ass.) column (4 mm i.d. \times 30 cm) was used with a linear gradient solvent system (a, H₂O + 0.2% H₃PO₄, pH 2.4; b, CH₃CN + 0.2% H₃PO₄; 12% B \rightarrow 24% B) over 20 min with a flow rate of 2.0 ml min⁻¹. Fractions (30-s) were collected and the radioactivity measured by liquid scintillation counting. Using this HPLC system we were able to monitor the metabolism of the ^3H -ligand after the binding assay and thus develop a mixture of peptidase inhibitors effective in stabilizing BK. This increase in BK stability and use of a ligand of 2-4 times higher specific activity accounts for the almost 10-fold greater detected affinity of BK for its receptor than published previously¹⁷. In all assays mucosa was separated from the muscle layers by scraping gently with a glass slide. Crude membranes were prepared by homogenizing tissues in 20 vol 25 mM TES, pH 6.8 + 1 mM 1,10-phenanthroline with a Brinkmann Polytron PT10 (setting 6 for 30 s). The homogenates were centrifuged twice at 50,000g for 10 min with an intermediate rehomogenization in buffer. For routine studies the final pellets were resuspended in 300 vol of incubation buffer (25 mM TES pH 6.8, 1 mM 1,10 phenanthroline, 0.2% BSA (Sigma; crystallized, lyophilized), 0.1 mM bacitracin, 1 mM dithiothreitol, 1 μM captopril). To triplicate polypropylene incubation tubes were added (in a total volume of 4 ml); 850 μl of freshly resuspended tissue, 25,000 d.p.m. of ^3H -BK (final concentration 0.05 nM) and competing agents. After incubation for 90 min at 4°C the samples were rapidly filtered over GF/B filters previously coated with 0.1% aqueous polyethyleneimine solution, then the filters were washed three times with 3 ml ice-cold buffer. Filter-bound radioactivity was determined by liquid scintillation counting at 40% efficiency in 10 ml Formula 947 (NEN). Typical c.p.m. were 1,000 total and 35 blank with a tissue concentration of 1 ml tissue wet weight per ml. For metabolism studies, samples were centrifuged after incubation and the supernatant analysed by HPLC. E_{max} ; maximal effect; EC₅₀, concentration to elicit 50% maximal effect relative to bradykinin E_{max} in stimulating I_{sc} in guinea pig ileum; IC₅₀, concentration of nonradioactive BK or BK analogue required to displace 50% of specifically bound ^3H -BK from its receptor EC₅₀ values represent mean \pm s.e.m.

Table 2 Effect of bradykinin on chloride fluxes

	m→s	Cl ⁻ flux s→m	Net
Control	8.2±0.8	8.7±0.8	-0.5±1.6
Bradykinin (10 ⁻⁵ M)	8.3±0.4	12.1±1.1*	-3.8±1.3*

Values are the μ equiv. $\text{cm}^{-2} \text{h}^{-1} \pm \text{s.e.m.}$ for six paired experiments. Two 10-min samples were taken starting 15–20 min after the addition of $^{36}\text{Cl}^-$ and 5 min after adding bradykinin. * $P < 0.025$. Fluxes were measured with tissues short-circuited as described previously¹⁸. Flux is from mucosa to serosa (m→s) or serosa to mucosa (s→m).

possible function of the mucosal receptors, we evaluated the influence of bradykinin on the transepithelial potential difference (p.d.) and short-circuit current (I_{sc}) of the mucosal layer of the guinea pig ileum using techniques previously described¹⁸ (Fig. 2, Table 1). Tissue conductance showed no appreciable change and therefore the change in I_{sc} was proportional to the change in p.d. There was no effect on p.d. or I_{sc} when bradykinin in concentrations up to 10 μM was added to the mucosal bathing solution. In striking contrast, addition of nanomolar concentrations of bradykinin to the serosal surface rapidly increased p.d. and I_{sc} , with maximal effects within 2 min (Fig. 2). The finding that bradykinin acts only when added to the serosal surface agrees with the localization of bradykinin receptors to the serosal surface of villus and crypt epithelium. These effects resemble those produced in this tissue by other peptides such as vasoactive intestinal peptide¹⁹, substance P²⁰, neurotensin²⁰ and bombesin²¹.

After quickly becoming maximal, the I_{sc} diminished with a rather slower time course similar to that observed for the 'fading' of the smooth muscle-contacting effects of bradykinin⁴. Whether it is related to tachyphylaxis or peptide metabolism is unclear. In the absence and presence of the kininase II inhibitor, captopril, 50% of the maximal response occurs at 10 and 1.0 nM bradykinin, respectively. With this 10-fold enhancement of potency, bradykinin has a similar potency in altering I_{sc} and binding to receptors (Table 1).

Several experimental results suggest that the bradykinin-induced increase in I_{sc} is due to stimulation of anion secretion. Thus, the effects of bradykinin on p.d. and I_{sc} are reduced by 86% when Cl^- and HCO_3^- are replaced by sulphate (data not shown). Other evidence derives from direct measurement of unidirectional Cl^- fluxes across the short-circuited ileal mucosa in the presence and absence of bradykinin (Table 2). In control tissues there is a mean net Cl^- secretion of 0.5 $\mu\text{equiv. cm}^{-2} \text{h}^{-1}$. In the presence of bradykinin, net Cl^- secretion increases to +3.8 $\mu\text{equiv. cm}^{-2} \text{h}^{-1}$. These experiments used high concentrations of bradykinin to obtain maximal and prolonged effects.

The effects of bradykinin do not seem to be mediated by influences on neuronal conduction, as they are not affected by tetrodotoxin (Table 3); calcium movements may be involved, as verapamil, a Ca^{2+} channel blocker, markedly inhibits the influences of bradykinin on I_{sc} (Table 3). Bradykinin stimulation of I_{sc} is also completely blocked following the addition of the Ca^{2+} channel blocker CoCl_2 (1 mM). A possible role of Ca^{2+} agrees with data that Ca^{2+} regulates intestinal secretion²² and bradykinin receptor binding¹⁷.

It also seems that the effects of bradykinin on Cl^- secretion may be mediated by arachidonic acid and its metabolites. We have found that the action of bradykinin can be inhibited by a variety of agents that act as inhibitors of cyclooxygenase (for example, indomethacin) and phospholipase A_2 (for example, mepacrine). Moreover, exogenously added arachidonic acid or prostaglandin E_2 (PGE_2) are both powerful secretory stimuli and bradykinin can stimulate the *in vitro* release of PGE_2 (ref. 23). Interestingly, phospholipase A_2 , the enzyme that releases arachidonic acid from membrane phospholipids, is dependent on calcium. Conceivably, bradykinin alters the availability of

calcium to phospholipase A_2 by opening calcium channels as indicated by the inhibitory effects of Ca^{2+} channel blockers.

The present results suggest that bradykinin may have both a physiological and pathological role in the intestine. Our *in vitro* findings are consistent with the observations of Hardcastle *et al.*¹⁵ that bradykinin causes a transient increase in transcolonic and transjejunal p.d. in the rat. Independently Cuthbert and Margolius^{24,25} have also found potent enhancement of gut chloride secretion by kallidin and have also suggested a role for prostaglandins. The bradykinin receptors in the crypts might regulate this anion secretion. Bradykinin may enhance intestinal absorption of amino acids and glucose^{25,26}, effects that could involve bradykinin receptors in the tips of the intestinal villi where such absorption takes place.

Autoradiography at the light microscopic level does not allow the precise determination of the cellular location of receptors. Bradykinin receptors in the lamina propria are probably located on the basolateral membranes of the epithelial cells, however, receptors may also occur on smooth muscle cells, blood vessels and/or sensory nerve fibres in the villi.

Excessive kinin activity might account for some pathological conditions. In carcinoid syndrome, serotonin may be responsible for some of the symptoms⁵⁻⁷. However, although serotonin does elicit diarrhoea²⁸, it causes vasoconstriction⁷ rather than the vasodilatation and the associated flushing, light-headedness and headache that typically occurs in carcinoid patients. Moreover, while some increase of blood level of serotonin occurs in certain patients with carcinoid syndrome, there is no correlation with the onset of their symptoms⁷. By contrast, increase blood levels of kinins have been detected in carcinoid patients in the course of their symptoms⁵⁻⁷.

Kinins could also play a part in inflammatory bowel disease. In these conditions the plasma levels of kinins correlate very closely with the onset of vasomotor and gastrointestinal symptoms⁶⁻⁹. As inflammation is associated with the formation of kinins²⁹, one would expect kinins to be released into the local or systemic circulation. Indeed, inflamed intestinal tissue

Fig. 2 Effect of BK on intestinal potential difference (p.d.). Ileal mucosa was obtained from female Hartley guinea pigs weighing 400–600 g. Segments of distal ileum, ~10–15 cm long, were excised 5 cm above the ileo-caecal junction. The segments were cut along their mesenteric border and placed in oxygenated ice-cold Ringer's. After stripping off the serosa and underlying longitudinal muscle layer, each tissue was mounted between two Leucite half chambers, the exposed areas being 0.64 cm^2 . The apparatus for measuring p.d. and I_{sc} was as described previously¹⁸. *a*, Effect of single dose of BK on transepithelial p.d. across guinea pig ileal mucosa. *b*, Effect of increasing concentrations of BK analogue (ThiAla^{5,8}) on p.d. Peptides were added at \uparrow . Tracings are from single experiments, but are characteristic of tracings from at least 10 other experiments.

Table 3 Effect of verapamil and tetrodotoxin on peak increments in I_{sc} elicited by bradykinin

	n	Response to 1.0 μ M bradykinin Change in I_{sc} on drug addition (μ A cm ⁻²)	(% of control response)
Tetrodotoxin	4	-44.4 \pm 4.8	119.4 \pm 17.1
Verapamil	4	-24.6 \pm 5.2	29.9 \pm 10.3*

Values are mean \pm s.e.m.; n, number of paired experiments. Negative values reflect decreases in I_{sc} . * $P < 0.01$ compared with control.

from patients with ulcerative colitis contains abnormally high levels of active kallikrein, the kinin-releasing enzyme¹⁴. Plasma and tissue levels of peptidyl dipeptidase which degrades kinins, are depressed in patients with regional enteritis; this would elevate kinin levels^{30,31}. Also, in regional enteritis plasma levels of α_2 -macroglobulin are reduced³². α_2 -Macroglobulin inhibits the bradykinin releasing enzyme kallikrein, thus reduced levels of the inhibitor should facilitate kinin synthesis. If indeed kinins are associated with symptoms of carcinoid syndrome or inflammatory bowel disease, then administration of the peptidyl dipeptidase inhibitor captopril to such patients may be contraindicated.

We thank Lynda Hester for technical assistance and Dr John Stewart, University of Colorado, for the gift of the bradykinin analogues. This work was supported by USPHS grants DA 02121, AM 21345, DA 00266 and NS 16374, and grants from the National Foundation of Ileitis and Colitis, the McKnight Foundation and RSA award DA 00074 to S.H.S.

A new look at nonparasitized red cells of malaria-infected monkeys

C. M. Gupta, A. Alam, P. N. Mathur & G. P. Dutta

Divisions of Biophysics & Microbiology,
Central Drug Research Institute, Lucknow-226001, India

Many reports have shown that malarial parasites can produce distinct morphological and molecular alterations in the membranes of the parasitized erythrocytes¹⁻⁸, but few studies have been carried out on nonparasitized erythrocytes of infected animals⁹⁻¹¹. We report here that the outer leaflet of the membrane bilayer of nonparasitized erythrocytes contains significantly larger amounts of aminophospholipids (phosphatidylethanolamine (PE) and phosphatidylserine (PS)), than the normal red cell membrane. This alteration in nonparasitized red cells is probably caused by Ca²⁺-induced cross-linking of spectrin, and gradually disappears after chloroquine treatment. The external localization of PS in these cells together with defective structure of their cytoskeletal network provide a strong basis for the complications associated with malaria infection like thrombosis, infarction and severe anaemia.

The transbilayer distributions of the diacylglycerophospholipids, phosphatidylcholine (PC), PE and PS, in the membranes of normal erythrocytes of uninfected monkeys as well as nonparasitized red cells of *Plasmodium knowlesi*-infected monkeys were investigated using phospholipase A₂ and 2,4,6-trinitrobenzenesulphonic acid (TNBS) as external membrane probes^{12,13}. The results shown in Table 1 reveal marked differences between the two types of cells after treatments with phospholipase A₂. Unlike the normal intact cells, PE (~31%) and PS (~15%) in nonparasitized erythrocytes from infected monkeys were readily accessible to the enzyme. Almost complete (92-100%) hydrolysis of all the glycerophospholipids occurred when unsealed ghosts of the normal and nonparasitized cells were separately treated, in identical conditions, with phospholipase A₂.

Treatments of both types of cells with TNBS also reflected notable differences (Table 2). In the nonparasitized cells, TNBS

Table 1 Erythrocyte phospholipid degradation by phospholipase A₂

Sample	n*	PC (%)	PE (%)	PS (%)
Normal red cells	15	57.35 \pm 4.11	0	0
Nonparasitized red cells	12	48.31 \pm 4.23	31.31 \pm 2.40	15.19 \pm 2.32

Synchronous infections of *Plasmodium knowlesi* (WI strain) were maintained in healthy rhesus monkeys as described earlier⁸. The monkeys were bled when parasites were at the schizont stage. Blood was drawn into heparinized glass tubes and washed three times with phosphate-buffered saline (pH 7.2). Leukocytes and platelets from normal blood and leukocytes, platelets and schizonts from infected blood were removed by means of a Ficoll-Hypaque gradient²⁶. The nonparasitized red cells thus obtained were invariably contaminated with <1% erythrocytes that were infected with early ring stage of *P. knowlesi*, as determined by Giemsa staining. Erythrocytes were treated with phospholipase A₂ (purified from *Naja naja* snake venom, Haefkin Institute, Bombay) essentially in the conditions described earlier⁸. After inhibiting the enzyme activity by addition of o-phenanthroline and EDTA²⁷, lipids were extracted from cells. The lipid mixture was chromatographed on silica gel G-60 TLC plates as described previously⁸ and the total phosphorus content in each spot was determined²⁸. The percentage of the total phospholipid hydrolysed after treatment of red cells with the enzyme was determined by measuring the ratio of remaining diacylglycerophospholipids to the corresponding lyso derivative. Values are expressed as mean \pm s.d. <5% cells were lysed under the experimental conditions. Unsealed ghosts, prepared²⁹ from both the normal and nonparasitized cells, were also treated with the enzyme in identical conditions. Almost complete (92-98%) hydrolysis of all the diacylglycerophospholipids was observed in both the cases. n, Number of determinations.

* Three determinations on each blood sample of five uninfected monkeys and four infected monkeys (parasitaemia 10-20%).

Table 2 Labelling of erythrocyte aminophospholipids with TNBS

Sample	n*	PE (%)	PS (%)
Normal red cells	12	18.55 ± 2.87	0
Nonparasitized red cells	9	34.89 ± 2.81	16.10 ± 2.43

Labelling of erythrocytes with TNBS was carried out according to the reported procedure³⁰. The incubations were done at 20° ± 2 °C for 4, 6 and 10 h. No differences in the percentage of labelling in these experiments were observed. No detectable cell lysis occurred in all these experiments. The percentage of TNBS labelling was determined by the total phosphorus determinations and also by measuring absorbance of yellow colour at 340 nm. Values shown are mean ± s.d.. All the aminophospholipids were completely labelled when unsealed membrane ghosts from both the normal and nonparasitized cells were treated with TNBS under identical conditions. n, Number of determinations.

* Three determinations on each blood sample of four uninfected monkeys and three infected monkeys (parasitaemia 10–20%).

modified both PE (~35%) and PS (~16%) whereas in the normal cells, only PE (~19%) was labelled by the reagent. The increased amounts of PE in the outer surface of the nonparasitized cells, as compared with the normal cells, did not arise from the transmembrane movement¹⁴ of this lipid from the inner to the outer surface of the cell membrane because almost equal amounts of PE were labelled when the cells were treated with TNBS for 4, 6 and 10 h. Also, the observed differences in the amounts of labelled aminophospholipids were not due to a partial reaction with reagents, as PE and PS were completely labelled when unsealed ghosts of the two types of cells were reacted with TNBS in identical conditions. Attempts were also made to use these methods to study the nonparasitized cells obtained from blood of monkeys which developed >30% parasitaemia. Invariably, extensive haemolysis of cells occurred on

exposing them to similar concentrations of phospholipase A₂ for relatively short periods of time and also during their treatment with TNBS for >4 h. However, the amounts of PS labelled by TNBS in 4 h in such cells were significantly larger (~40%) than those observed in the nonparasitized cells of monkeys with parasitaemia (10–20%).

Accessibility of different phospholipids to phospholipases and TNBS in intact red cells has been correlated with their localization in the external leaflet of the membrane bilayer^{11,12}. From this study, it appears that parasitization of erythrocytes by the malarial parasite not only alters the phospholipid asymmetry in the parasitized cell membrane⁸, but also leads to an enormous change in the transbilayer distributions of various phospholipids in nonparasitized erythrocyte membrane. As shown in Table 1, the amounts of PC in the outer surface of the nonparasitized cells seem to be less than in normal cells. This redistribution of PC may have occurred to compensate for the increased amounts of PE and PS in the outer surface.

The above studies were carried out on a group of four infected monkeys. The same monkeys were treated with chloroquine (20 mg per kg for 3 days). This treatment completely removed circulating parasites. Similar doses of chloroquine were also given to a group of three uninfected monkeys. Determinations of transbilayer phospholipid distributions in the erythrocyte membrane on day 30 after treatment of the infected monkeys with the drug, revealed that appreciable amounts of PS (5–8%) were still present in the outer surface whereas amounts of the external PE (18–22%) in these cells were similar to those of the normal erythrocytes. Unlike the normal erythrocytes, phospholipase A₂ could still degrade PE (9–14%) in these cells.

Table 3 Concentrations of GSH in erythrocytes

Sample	n	GSH (μmol per ml packed cells)
Normal red cells	10	2.2 ± 0.7
Nonparasitized red cells*	6	1.9 ± 0.3

Concentrations of GSH in red cells were determined by the procedure of Beutler *et al.*³¹. Values are expressed as mean ± s.d.; n, number of animals.

* Parasitaemia 10–20%.

Fig. 1 Densitometer scans of gels stained for proteins with Coomassie blue after electrophoresis of red cell ghosts on polyacrylamide gels in the presence of SDS (ref. 22). *a*, Normal monkey erythrocyte ghosts; *b*, ghosts of nonparasitized erythrocytes of *P. knowlesi*-infected monkey (parasitaemia ~12%). The protein bands of the normal monkey erythrocyte are numbered according to the nomenclature of Fairbanks *et al.*²². TD, tracking dye.

However, by day 60, the amounts of PE (16–20%) and PS (none) in the external surface were normal. Chloroquine treatments of uninfected monkeys had no effect on red cell membrane phospholipid asymmetry.

Recent studies have shown that strong interactions between aminophospholipids and cytoskeletal proteins (specifically spectrin) probably determine phospholipid asymmetry in the erythrocyte membrane^{15–17}. This asymmetry in red cells is lost if the spectrin component of the cytoskeletal network becomes defective^{14,15}. Defects in the structure of spectrin may originate from decreased concentrations of glutathione (GSH) or from elevated levels of Ca²⁺ in cells^{18–21}. To look at this, membrane proteins of nonparasitized red cells were analysed by SDS-polyacrylamide gel electrophoresis²². Similar studies were also carried out on normal red cells of a group of six uninfected monkeys. The gel profiles of membrane proteins of nonparasitized erythrocytes from five different monkeys (parasitaemia 10–20%) invariably showed two additional high molecular weight protein bands (α and β , Fig. 1*b*) of variable intensity, which were absent in the gel profiles of the normal cell ghosts (Fig. 1*a*). No correlation was found between the intensity of the two bands and the extent of parasitaemia in monkeys. From a comparison between the relative intensities of protein bands present in the gel profiles of normal and nonparasitized erythrocyte ghosts, it appears that the two protein bands arise from cross-linking of spectrin. To examine whether these bands originate from oxidation of sulphhydryl groups of the protein¹⁵, the nonparasitized cell ghosts were incubated with dithiothreitol at 37 °C for 60 min before their extraction. This treatment had no effect on these bands, implying that the two high molecular weight proteins did not arise from oxidation of sulphhydryl

Table 4 Ca^{2+} contents of normal red cells of uninfected monkeys and non-parasitized erythrocytes of *P. knowlesi*-infected monkeys

Sample	n	Ca^{2+} (μg per ml packed cells)
Normal red cells	5	0.61 ± 0.39
Nonparasitized red cells*	6	2.36 ± 1.67

Ca^{2+} content in red cells was determined by atomic absorption spectrophotometry as described by Harrison and Long²².

* Parasitaemia 10–20%.

groups of spectrin. This is further supported by our finding that almost equal concentrations of GSH were present in normal as well as nonparasitized cells (Table 3). Nevertheless, the Ca^{2+} levels in the two types of cells were significantly different (Table 4). The elevated levels of Ca^{2+} present in the nonparasitized cells are compatible with earlier findings that malaria infection in animals results in diminished levels of ATPase activity in parasitized as well as nonparasitized red cells¹⁰. A partial (or complete) deactivation of ATPase in these cells would result in the elevated levels of Ca^{2+} and consequently activation of transglutaminase which may induce cross-linking of spectrin in the nonparasitized cells^{18–20}.

Normal structure of spectrin seems essential for the invasion of red cells by the malarial parasite²³. This means that if the structure of this protein becomes defective in the total population of nonparasitized erythrocytes in a malaria-infected animal then further invasion would not proceed. That parasitaemia does regularly increase in the infected monkeys suggests that only a fraction of the total population of the nonparasitized cells becomes abnormal. This conclusion is supported by the observation that unlike the nonparasitized cells, erythrocytes containing malarial parasite at the early ring stage have PS located exclusively in the inner leaflet of the membrane bilayer⁸.

Previous findings^{9,10} indicate that the serum of malaria-infected animals contains some unknown factors which induce changes in the nonparasitized cells. We, therefore, incubated normal erythrocytes with serum of heavily infected monkeys at 37 °C for 2–3 h. Treatments of such cells with TNBS and phospholipase have so far not revealed any effect of the serum but further studies are in progress.

These observed abnormalities suggest that externalization of PS in these cells could enhance blood coagulation^{24,25} and, therefore, may cause thrombosis. Also these cells, because of their defective cytoskeletal network, would be rapidly cleared from the circulation by the spleen¹⁸, making the animals more anaemic.

We thank Dr Nitya Nand for his help and the Council of Scientific and Industrial Research, New Delhi, for award of a fellowship to A.A. The *Plasmodium knowlesi* strain was a gift from Professor P. Garnham. This report is communication No. 3139 from CDRI, Lucknow.

Restriction of alternative complement pathway activation by sialosylglycolipids

Noriko Okada*, Tatsuji Yasuda† & Hidechika Okada‡

Although sheep erythrocytes do not activate the alternative complement pathway (ACP) of human serum, the erythrocytes gain a capacity to activate human ACP following removal of membrane sialic acid by neuraminidase treatment^{1–3}. Therefore, asialoglycoconjugates generated from sialosylglycoconjugates by neuraminidase treatment might be responsible for this type of ACP activation on cell membrane⁴. Alternatively certain sialosylglycoconjugates on the cell membrane might restrict the activation of ACP and removal of the terminal sialic acid from the glycoconjugates would abolish this restricting capacity and result in activation of the ACP on the cell membrane⁵. To determine which of the above two possible mechanisms is the case, we used a liposome model membrane in which glycolipids could be artificially inserted, and our results suggest that the latter of the two possible mechanisms is the case.

A standard liposome preparation was prepared with cholesterol and dimyristoylphosphatidylcholine (DMPC) at an equimolar ratio. To prepare liposomes with test glycolipids inserted, cholesterol, DMPC and the test glycolipid were mixed in chloroform/methanol (2:1) at a molar ratio of 1.0:1.0:0.1 and the solvent evaporated, leaving a lipid film in a rotatory evaporation flask. On the dried film of lipid, 0.2 M carboxyfluorescein (CF) was added and the lipid dispersed at 60 °C by vigorous shaking. Thus prepared liposomes were washed with gelatin veronal-buffered saline (GVB, pH 7.4) by centrifugation at 15,000 r.p.m. for 20 min. The liposomes with inserted

Table 1 Chemical structures of glycolipids used

Glycolipid	Chemical structure
GM3	NA-Gal-Glc-ceramide
GM1	Gal-GalNac-Gal-Glc-ceramide
	NA
SPG	NA-Gal-GlcNac-Gal-Glc-ceramide
CMH	Gal-ceramide
CDH	Gal-Glc-ceramide
CTH	Gal-Gal-Glc-ceramide
GA2	GalNac-Gal-Glc-ceramide
GA1	Gal-GalNac-Gal-Glc-ceramide
Globoside	GalNac-Gal-Gal-Glc-ceramide
PG	Gal-GlcNac-Gal-Glc-ceramide

SPG, sialosylparagloboside; CMH, galactocerebroside; CDH, lactosylceramide; CTH, ceramidetrihexoside; GA2, asialo-GM2; GA1, asialo-GM1; PG, paragloboside; NA, neuraminic acid; Gal, galactose; Glc, glucose; GalNac, N-acetylgalactosamine; GlcNac, N-acetylglucosamine.

Fig. 1 Lysis of liposomes incorporated with glycolipids induced by 1:4 dilution of C4D-GPS (open bars) or human serum (solid bars) in Mg^{2+} -EGTA-GVB. To 50 μ l of a 1:4 dilution of C4D-GPS or human serum in Mg^{2+} -EGTA-GVB, 5 μ l of liposome solution (the concentration of liposome was adjusted to correspond to 0.05 mM phosphorus) in GVB were added and the mixture incubated at 25 °C for 60 min. After incubation, 2.0 ml of EDTA-VBS were added to each reaction mixture and the fluorescent intensity of CF release determined by excitation at 490 nm and emission at 520 nm. The 100% marker release was achieved by lysing liposomes with Triton X-100 as described previously⁷. Human serum did not lyse liposomes incorporated with any of the glycolipids. Although C4D-GPS lysed liposomes with paragloboside (PG), antibody against PG was detected. After heat inactivation at 56 °C, the C4D-GPS was diluted in GVB²⁺ (GVB containing 0.15 mM $CaCl_2$ and 0.5 mM $MgCl_2$) and incubated with PG-inserted liposomes in the presence of fresh human serum to detect antibody activity to PG by classical complement pathway-mediated liposome lysis. Antibody against PG was detected up to a 1:263 dilution of the heated C4D-GPS. Therefore, no glycolipids were found which induce ACP-mediated liposome lysis by C4D-GPS or human serum in the absence of antibody reaction.

glycolipids were then incubated at 25 °C for 60 min with C4-deficient guinea pig serum (C4D-GPS) or human serum diluted 1:4 in Mg^{2+} -EGTA-GVB (GVB containing 2 mM $MgCl_2$ and 10 mM ethyleneglycol-bis(β -aminoethyl ether) N,N' -tetraacetate, pH 7.4). Mg^{2+} -EGTA-GVB was used to inhibit complement activation via the classical pathway which requires Ca^{2+} at the reaction of the first component of complement, C1. After incubation, the amount of CF marker released from the liposomes was determined by excitation at 490 nm and emission at 520 nm following dilution with EDTA-VBS (veronal-buffered saline containing 10 mM EDTA pH 7.4) as described elsewhere^{6,7}. However, no glycolipid including the asialo-type glycolipids such as CDH, GA1 and GA2 (see Table 1 for their structure) made liposomes reactive with guinea pig or human complement via the alternative pathway except where the serum used for the complement source contained natural antibody against the glycolipid inserted (Fig. 1). These results indicated that glycolipids including asialo-type glycolipids have no capacity to activate ACP in the absence of specific antibody.

Recently we found that liposomes inserted with trinitrophenylaminocaproyldipalmitoylphosphatidylethanolamine (TNP-Cap-DPPE) can be lysed by guinea pig complement via ACP activation⁷. Therefore, glycolipids were inserted onto the membrane of liposomes with TNP-Cap-DPPE (TNP-Cap-liposomes) to examine the effect of the glycolipids on the ACP-activating capacity of TNP-Cap-liposomes. TNP-Cap-liposomes with inserted test glycolipids were composed of cholesterol, DMPC, TNP-Cap-DPPE and the test glycolipids at a molar ratio of 1.0:1.0:0.05:0.1, respectively. The reactivity

of the liposomes with guinea pig ACP was examined by the release of CF marker from liposomes as described previously⁷. Sialosylglycolipids [GM3, GM1 and sialosylparagloboside (SPG)] inserted onto the liposome membrane of TNP-Cap-liposomes markedly inhibited the lysis of the liposomes by C4D-GPS in Mg^{2+} -EGTA-GVB (Fig. 2). It was possible that sialosylglycolipids such as GM3 made the liposomes resistant to complement attack and that the TNP-Cap-liposomes with the said glycolipids were not lysed by complement although they activated guinea pig ACP. However, this was not the case as the insertion of GM3 to TNP-Cap-liposomes also suppressed the capacity of the liposomes to consume guinea pig complement. Briefly, C4D-GPS diluted 1:2 in Mg^{2+} -EGTA-GVB was mixed with an equal volume of TNP-Cap-liposomes, TNP-Cap-liposomes with GM3, TNP-Cap-liposomes with CDH, and liposomes composed of only DMPC and cholesterol. Those liposomes were not carrying the CF marker and had been suspended at 5 mM phosphorus of DMPC. After incubation at 25 °C for 60 min, the reaction mixtures were centrifuged at 15,000 r.p.m. for 20 min. The supernatants were diluted in Mg^{2+} -EGTA-GVB and incubated with TNP-Cap-liposomes to determine the residual lytic activity on the liposomes via ACP activation. Preincubation of C4D-GPS with TNP-Cap-liposomes and TNP-Cap-liposomes containing CDH consumed over 90% of the complement activity while pretreatment with

Fig. 2 Lysis of TNP-Cap-liposomes with inserted glycolipids by 1:4 (open bars) or 1:8 (solid bars) dilutions of C4D-GPS in Mg^{2+} -EGTA-GVB. Liposomes were incubated at 25 °C for 60 min with C4D-GPS and CF marker release was determined as described in Fig. 1 legend. The extent of liposome lysis was expressed as the corrected per cent marker release which was calculated as a percentage of the maximum release of CF by complement-mediated liposome lysis. The maximum release was determined by lysing liposomes with a 1:10 dilution of Hartley guinea pig serum in the presence of heat-inactivated rabbit anti-serum to TNP in GVB²⁺. The maximum release was approximately 70% of the total releasable CF in the liposomes by Triton X-100. We used the corrected per cent marker release, as the extent of possible release by complement attack varied to some degree among liposome preparations. Sialosylglycolipids (GM3, GM1 and SPG) exhibited remarkable inhibition of lysis in Mg^{2+} -EGTA-GVB by C4D-GPS in liposomes to which sialosylglycolipids were inserted. Enhanced lysis of TNP-Cap-liposomes with PG was due to the presence of antibody to PG in the C4D-GPS. TNP-Cap-liposomes also activate the classical complement pathway (CCP) of guinea pig⁷ as well as ACP. Therefore, TNP-Cap-liposomes with glycolipids were also incubated with Hartley guinea pig serum in GVB²⁺ to determine the effect of glycolipids on CCP-mediated liposome lysis. However, no inhibition of the CCP-mediated liposome lysis was noted upon insertion of the sialosylglycolipids, indicating that they inhibit complement activation via the ACP but not by the CCP.

Fig. 3 Lysis by C4D-GPS of TNP-Cap-liposomes having incorporated varying amounts of GM3 onto the membrane. The membrane compositions of the liposomes were cholesterol/DMPC/TNP-Cap-DPPE/GM3 = 1.0:1.0:0.05:0.1 (Δ), 1.0:1.0:0.05:0.03 (▲), 1.0:1.0:0.05:0.01 (○), or 1.0:1.0:0.05:0 (●). Liposomes were incubated with C4D-GPS serially diluted in Mg^{2+} -EGTA-GVB and lysis was determined by CF marker release. GM3 incorporated liposome lysis was inhibited in a dose-dependent manner.

TNP-Cap-liposomes containing GM3 consumed only 40% of the complement activity. This result indicated that incorporation of GM3 onto TNP-Cap-liposomes inhibited the ACP activation on the liposomes.

On the other hand, CDH and GA1 which were asialo-type glycolipids of GM3 and GM1 respectively, did not affect the ACP-activating capacity of TNP-Cap-liposomes to which they were inserted. This suggests that sialosylglycolipids on cell membranes restrict the activation of ACP, and that removal of sialic acid from the glycolipid abolishes the restricting capacity which allows the activation of ACP on cell membrane.

To examine the amount of GM3 required for the restriction of ACP activation on TNP-Cap-liposomes, varying quantities of GM3 were inserted onto the liposomes. GM3 incorporated onto TNP-Cap-liposomes at a molar ratio to DMPC of as low as 0.01 can still inhibit ACP activation by TNP-Cap-liposomes (Fig. 3).

As sialosylglycolipids create a negative potential on the liposome surface, it was considered that the negative potential might play some part in the restriction of ACP activation on TNP-Cap-liposomes. However, positively charged amphiphiles such as stearylamine, and negatively charged ones such as dicetylphosphate and dipalmitoylphosphatidic acid, had no effect on ACP activation by the TNP-Cap-liposomes to which they were inserted⁷. Therefore, the restricted ACP activation on TNP-Cap-liposomes with sialosylglycolipids was not merely due to the negative potential on the membrane caused by the glycolipids. Sialosylglycolipids might interact with C3b molecules generated by the initial C3 convertase, C3(H₂O)Bb, which is made in serum in physiological conditions by the reaction of spontaneously hydrolysed C3 (at thiolester bond in α -chain) with factor B (ref. 8), and the C3b molecules interacted with sialosylglycolipids might be promptly inactivated by regulatory proteins in serum, factors H and I, resulting in the inhibition of the amplification reaction of C3b molecules which would otherwise form new C3 convertases with factor B, causing a positive feedback circuit in ACP activation^{9,10}.

As demonstrated above, sialosylglycolipids, and possibly sialosylglycoproteins, are thought to have a role in restricting undesirable amplification of ACP reaction, especially on self cell membranes. However, in addition to the glycolipid-mediated restriction of ACP activation on the cell membrane, some other mechanisms in the regulation of ACP activation on cell membranes such as C3b receptor-mediated restriction¹¹⁻¹³ remains

to be studied, as neuraminidase-treated cells do not activate homologous ACP^{11,14} although they activate heterologous ACP¹⁻³. This may lead to the clarification of the mechanism(s) by which complement recognition of the normal self cell membrane is achieved and how restriction of the complement reaction is maintained.

We thank Professors T. Tsumita and A. Gohda for encouragement, and Miss Y. Koga for editorial assistance. This work was supported by Grants-in-Aid from the Japanese Ministry of Education, Science and Culture, and the Adult Disease Clinic Memorial Foundation.

Is nasal adenocarcinoma in the Buckinghamshire furniture industry declining?

E. D. Acheson, P. D. Winter, E. Hadfield & R. G. Macbeth

MRC Environmental Epidemiology Unit, University of Southampton, Southampton General Hospital, Southampton SO9 4XY, UK and the Department of Ear, Nose and Throat Surgery, High Wycombe General Hospital, Buckinghamshire HP11 2TT, UK

Since adenocarcinoma of the epithelium of the nasal cavity and accessory sinuses was recognized to occur more commonly in woodworkers in the British furniture industry than in other men^{1,2} and was prescribed as an industrial disease³, it has been found to occur in the furniture industry in many other countries. Here we review the incidence of the disease in Buckinghamshire up to the end of 1981 and report that skilled furniture makers such as wood machinists and cabinet and chair makers have experienced a cumulative lifetime risk of having nasal adenocarcinoma of at least 1 in 120 during the period studied. An analysis according to birth cohorts suggests that the disease may have reached its peak in men who entered the industry in the years 1915-24 but the apparent decline in incidence in men entering thereafter is not statistically significant. We argue that the carcinogen is almost certainly present in wood dust and point to the absence of recent quantitative data about dust levels in British furniture factories.

We studied the cases of nasal adenocarcinoma registered with the Oxford Regional Cancer Register between 1945 and the end of 1981. The Register includes data from the county of Buckinghamshire and the town of High Wycombe, one of the centres of the British furniture industry. Our estimates of the working population at risk have been derived from a register of 5,371 past and present workers in the Buckinghamshire furniture industry⁴ assembled (with the cooperation of the High Wycombe Furniture Manufacturers Association) by means of a letter sent to all member firms. Nine firms kept records containing sufficient identifying data to allow a follow-up. The

Table 1 SCIR for nasal adenocarcinoma in four birth cohorts of Buckinghamshire furniture workers

Birth cohort	Median year of entry to industry	Observed cases	Expected cases	SCIR (95% confidence intervals)
1890-99	1910	5	9.26	54 (18-126)
1900-09	1920	23	17.33	133 (84-199)
1910-19	1930	16	15.03	106 (61-173)
1920-29	1940	4	6.38	63 (17-161)
Total		48	48.00	100

register consists of men whose details had been recorded and retained by at least one of the nine firms and who had worked in one or more of these firms before the end of 1968. Men born after the beginning of 1940 were excluded. The nine firms comprise only 40% of the workforce in the Buckinghamshire furniture industry but are assumed to be representative of age, occupation and duration of service.

Man-years at risk were calculated for the periods 1945-68 and 1969-81, in 10-yr age groups. As the men on the register have so far only been followed up in respect of death from all causes to the end of 1968, the man-years at risk for 1969-81 were adjusted by the Buckinghamshire age-specific death rates taken from the 1969-73 Area Mortality Tables. The man-years at risk in the Buckinghamshire furniture industry for the period 1945-81 were then obtained by multiplying adjusted data from the register by the factor 2.5.

Standardized cohort incidence ratios (SCIR) were computed after Beral *et al.*⁵. Overall age-specific incidence rates were applied to the man-years at risk for individual cohorts to obtain expected numbers of cases, and confidence intervals were computed by assuming the observed number of cases to be a Poisson variable with expectation equal to the expected number of cases.

A total of 53 men who had worked at some time in the Buckinghamshire furniture industry are known to have developed nasal adenocarcinoma between the end of the Second World War and the end of 1981. Three of these (two cabinet makers and a machinist) had left Buckinghamshire before developing the tumour and were considered further only in computing the cumulative life risk of nasal adenocarcinoma in skilled furniture workers. Of the 50 men remaining, 16 were cabinet or chair makers, 22 were wood machinists including 2 turners, 5 were veneers, 3 were sanders or benchmen and 2 were French polishers. Two were unskilled: a labourer in the sawmill of a furniture factory and a man who maintained woodworking machinery.

Although there were more cases of nasal cancer in 1960-69 (20 cases) and 1970-79 (17 cases) than in 1950-59 (8 cases), the age at which the tumours were diagnosed increased over the period. The proportions of patients over 55 yr old for the periods 1945-64 and 1965-81 were significantly different ($\chi^2 = 11.4$, 1 d.f.; $P < 0.01$).

In Table 1 the 48 skilled men have been allocated to birth cohorts. The results show that the incidence ratio for nasal adenocarcinoma increased to a maximum for the men born

during 1900-09 (whose median year of entry to the industry was ~1920) and has declined thereafter. However, the decline is not statistically significant ($\chi^2 = 2.14$, 1 d.f.; $P > 0.1$)⁶. Neither computing the expected numbers on the basis of 5-yr as opposed to 10-yr age groups, nor excluding the 1890-99 cohort from the analysis alters the conclusion that there was a decline in the incidence experienced in the last three cohorts, but that it is not statistically significant.

The incidence of nasal adenocarcinoma among skilled woodworkers in the furniture industry—SCIR 147 (95% confidence interval = 108-194)—was more than 12 times that among the other employees in the industry (SCIR 12; 95% confidence interval = 0-32). No significant difference was found between the incidence in the two principal groups of skilled woodworkers, cabinet makers and wood machinists. Those affected were all men who had worked in close proximity to cutting or sanding, which creates large quantities of wood dust. The risk of a skilled woodworker in the Buckinghamshire furniture industry suffering from a nasal adenocarcinoma in his lifetime during the period of study has thus been about 1 in 120. This value is probably an underestimate as it is unlikely to include all the men who developed the tumour after leaving the area. During 1945-81 no case of adenocarcinoma is known to have occurred in a carpenter or joiner or in a wood machinist working outside the furniture industry in Buckinghamshire, although there are at least as many such woodworkers as in the furniture industry. Only five cases of adenocarcinoma occurred in Buckinghamshire men in other occupations during the same period.

For 40 of the 48 skilled woodworkers who developed nasal adenocarcinoma, we were able to obtain information about the period of time spent in the furniture industry. Two men had worked less than 5 yr, three between 5 and 20 yr, and 35 had worked more than 20 yr in the industry (Table 2). A comparison of those who had spent less than 20 yr in the industry with those who had worked 20 yr or more, revealed SCIR of 31 (95% confidence interval = 10-72) and 147 (confidence interval = 102-204), respectively. The risk of nasal cancer is thus significantly greater in men who have served longer in the industry.

None of the cases reported in Buckinghamshire presented less than 25 yr after first exposure. In the 42 patients for whom there was sufficient information, the average period from first exposure to diagnosis was 43.9 yr. Our best estimate of the temporal pattern of nasal adenocarcinoma occurrence in the Buckinghamshire furniture industry (Table 1) suggests that the epidemic reached its peak in skilled men born during the years 1900-09 (who entered apprenticeship between 1915-25) and has begun to decline in those entering in 1924-35 and 1935-44. This pattern will have been distorted if the ascertained proportion of the total number of cases occurring altered during the period. As the Oxford Cancer Register was not fully effective until 1956, it is possible that our estimate of the incidence in the 1890-99 cohort is low. However, a search of the High Wycombe death registers suggests that the disease was extremely rare before the Second World War². In any event, exclusion of the 1890-99 cohort from the analysis does not alter the apparent decline in the incidence of nasal cancer in those entering the industry since 1925.

It is possible also that the proportion of cases brought to our attention has increased recently; such a distortion would reduce the impact of a real decline in the disease. One of us (R.G.M.) has offered a screening service to furniture workers in the High Wycombe area since 1969; as a result of this, 4 of 19 patients with nasal adenocarcinoma in furniture workers resident in Buckinghamshire have been diagnosed since 1970. It seems likely that these tumours would otherwise have been diagnosed later in the illness. The fact that, recently, nasal cancer has occurred in older men is in part explained by the aging of the workforce. Another possible source of bias is our assumption that the age distribution of the men who worked for the nine firms is representative of Buckinghamshire furniture workers as a whole.

Table 2 Cases of nasal adenocarcinoma observed and expected and SCIR in Buckinghamshire furniture workers by duration of work in the industry

Years of work in industry	Observed cases 1945-79	Expected cases	SCIR (95% confidence intervals)
Under 5	2	5.56	36 (4-130)
5-9	1	3.47	29 (1-161)
10-19	2	7.14	28 (3-101)
20+	35	23.84	147 (102-204)
Total	40	40.00	100

See text for method of computation of man-years at risk.

The fact that the furniture workers with nasal cancer whose cases are reported here had first entered the furniture industry before the Second World War does not necessarily mean that the carcinogen is no longer present in the working environment. Three cases of nasal adenocarcinoma in men who entered the furniture industry in other areas of England shortly after the Second World War have been reported to us and cases in men who entered the industry during the war have been reported in France and Italy^{7,8}.

Nasal adenocarcinoma is now known to have been a special risk to furniture makers elsewhere for several decades and in Britain since 1920 and possibly earlier. This widespread occurrence, together with the fact that woodworking machinists (who saw the timber) and the cabinet and chair makers (who shape, finish, sand and assemble the furniture) experience similar risks make it unlikely that the tumours are due to a chemical agent applied to the wood at a particular stage of the process but more probably to a substance in wood dust itself. Occupational histories show that men exposed exclusively to beech and oak have developed tumours, but a wider range of hardwoods is probably implicated. It is unknown whether the absence of an excess risk of tumours in carpenters and joiners is due to the exposure of these men to low concentrations of dust particles of the appropriate size or because the carcinogen is absent from soft woods.

Prolonged inhalation of dust by furniture workers has been shown to impair mucociliary clearance and to lead to squamous metaplasia. Deposits of dust have been observed in the noses of furniture workers, on the mucosa close to the ethmoid bulla where the tumours are believed to originate⁹. The nature of the substances in wood dust which bring about these changes and which initiate carcinogenesis is unknown. Far from being an inert material as was believed previously, wood contains a wide range of biologically active substances including flavonols, other phenolic compounds and many terpenoids, some of which probably exert a protective function in timber as natural insecticides and fungicides. It is possible that one or more of these may be carcinogenic. Another possibility is that carcinogens may be formed by pyrolysis during machining. As nasal cancer in boot and shoe operatives is limited to men and women exposed to dust associated with preparing and finishing leather for heels and soles—which is usually tanned with vegetable extracts including extracts of wood—it is possible that these cancers also may be caused by a carcinogen derived from wood¹⁰. Systematic studies of the carcinogenicity of wood and leather dust are needed.

Although nasal cancer in furniture makers was prescribed as an industrial disease in 1969, there are no data indicating whether dust levels in British furniture factories have subsequently declined. A study of Buckinghamshire furniture factories published in 1974 showed that the average dust concentration was $\geq 5 \text{ mg ml}^{-1}$ (ref. 11). In 1976 a regulation was introduced in the United Kingdom requiring 'efficient exhaust ventilation' in furniture factories¹² but it is unknown whether this regulation has brought an improvement in dust levels.

We thank Miss Corinne Hunt and the staff of the Oxford Regional Cancer Register and the High Wycombe Furniture Makers Association for their help with this study.

Loss of intervening sequences in genomic mouse α -globin DNA inserted in an infectious retrovirus vector

Kunitada Shimotohno* & Howard M. Temin

McArdle Laboratory, University of Wisconsin, Madison, Wisconsin 53706, USA

Genes lacking the intervening sequences that are present in otherwise apparently homologous genes have been found in some highly oncogenic retroviruses (some viral oncogenes) and in the normal cell genome (cDNA genes, pseudogenes or processed genes)^{1–10}. Such cDNA genes might have arisen by reverse transcription of the spliced (intervening sequences removed) RNA transcript of the homologous genes. Another possible way for genes with intervening sequences to lose such sequences would be during replication in a retrovirus vector. To test this hypothesis we inserted genomic mouse α -globin DNA containing two intervening sequences¹¹ into the DNA of an infectious retrovirus vector¹² and report here that the intervening sequences were removed from DNA of progeny virus during virus replication.

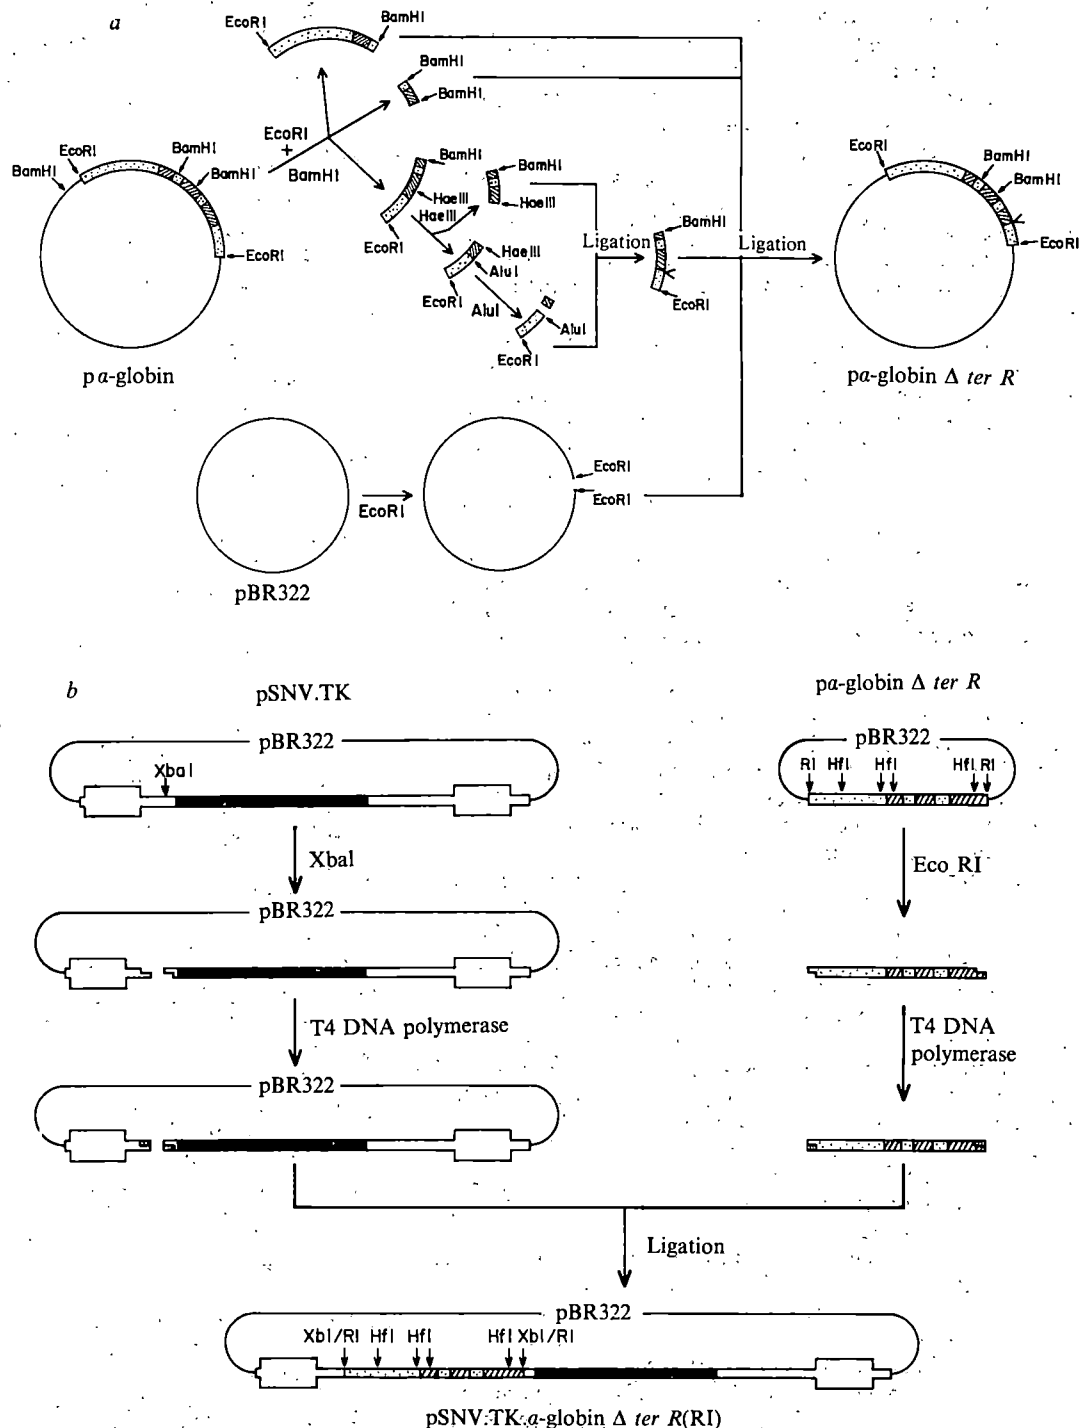

We previously found that removal of the 3' terminus of a thymidine kinase (TK) gene before its insertion in our infectious spleen necrosis virus (SNV) vector increased the recovery of infectious virus¹². Therefore, we prepared DNA of mouse α -globin without 3'-terminal sequences including the site of poly(A) addition (α -globin Δ terR gene) by removing 130 base pairs (bp) from the gene. The sequences removed were from 25 bp after the end of the coding sequences for protein (*Hae*III cleavage site) to 65 bp after the end of the sequences for mRNA (*Alu*I cleavage site) (Fig. 1a, also see map in Fig. 3).

The *Eco*RI- or *Hin*FI-digested α -globin Δ terR was then inserted into the *Xba*I cleavage site 40 bp (13 amino acids) inside the *gag* gene¹³ of a herpes simplex virus thymidine kinase Δ terR gene-containing retrovirus vector in which retrovirus sequences from approximately 1 to 7 kbp had been deleted¹⁴. (This vector is produced in mixed infection at approximately the same rate as a non-defective helper retrovirus¹⁴.) The strategy used for this insertion maintained both the *Xba*I and the *Eco*RI cleavage sites, pSNV-TK- α -globin Δ terR (RI), or *Hin*FI cleavage sites, pSNV-TK- α -globin Δ terR (*Hin*FI), at the ends of the vector and the α -globin Δ terR DNA (map in Fig. 1b).

To recover infectious virus carrying the α -globin DNA, pSNV-TK- α -globin Δ terR (RI) DNA was co-transfected into chicken cells with one tenth as much DNA of a provirus clone of a non-defective helper virus, reticuloendotheliosis virus strain A (REV-A). The virus produced was first assayed by its thymidine kinase transforming activity in buffalo rat liver (BRL) TK⁻ or chicken TK⁻ cells¹². SNV-TK- α -globin Δ terR (RI) was recovered at ~10% the yield of the parental SNV-TK; and SNV-TK α -globin Δ terR (*Hin*FI) was produced at about 30% of the yield of SNV-TK (data not shown). Therefore, sufficient recombinant thymidine kinase-containing virus was produced for a direct examination of its structure. Virus recovered 5 days after transfection with pSNV-TK- α -globin Δ terR (RI) $\sim 10^4$ – 10^5 TK-forming units per ml) was used to infect fresh chicken embryo fibroblasts. Three days later unintegrated linear viral DNA was prepared, digested with *Hin*FI, *Xba*I or *Eco*RI, and analysed (Fig. 2). Two bands, of 1.9 and 1.7 kbp, that hybridized to α -globin DNA were found after digestion with *Xba*I or *Eco*RI. The upper band is the same size as the parental α -globin Δ terR; the lower band about 250 bp smaller (see maps in Fig. 3). This difference in size is consistent with the absence of both intervening sequences from the DNA in the lower band (IVS-1 is 122 bp and IVS-2 is 134 bp¹¹). Digestion with *Hin*FI also resulted in two bands, of 810 and 560 bp, that hybridized

* Present address: National Institute of Genetics, Mishima, 411 Japan.

Fig. 1 Construction of recombinant DNAs. **a**, Construction of α -globin: $\Delta terR$: α -globin (200 μ g) was digested with *Eco*RI (New England Biolabs) at 37 °C for 10 h. The digest was analysed by electrophoresis into a 1% agarose gel at 30 V for 12 h. A fragment of 2 kbp (α -globin) was isolated from the gel²¹, digested with *Bam*HI (New England Biolabs), and the digest analysed by electrophoresis into a 1% agarose gel. DNA fragments of 1.2 (*Eco*RI/*Bam*HI), 0.3 (*Bam*HI/*Bam*HI), and 0.6 (*Bam*HI/*Eco*RI) kbp were isolated from the gel. The 0.6-kbp (*Bam*HI/*Eco*RI) fragment was digested then with *Hae*III (New England Biolabs), which digests between the C-terminal end of the protein and AATAAA in the untranslated region of the sequence (see map in Fig. 3), and the digest was analysed by electrophoresis into a 6% acrylamide gel. DNA fragments of 0.3 (*Bam*HI/*Hae*III) and 0.32 (*Hae*III/*Eco*RI) kbp were isolated from the gel. The fragment of 0.32 kbp (*Hae*III/*Eco*RI) was digested with *Alu*I (New England Biolabs), which digests after the site of poly(A) addition (ref. 11, also see map in Fig. 3), and the digested DNA was analysed by electrophoresis into a 6% acrylamide gel. A DNA fragment of 0.2 kbp (*Alu*I/*Eco*RI) was isolated from the gel. Equimolar amounts of the *Bam*HI-*Hae*III fragment of 0.3 kbp and the *Alu*I-*Eco*RI fragment of 0.2 kbp were ligated with T4 DNA ligase (NEN) at 24 °C for 17 h to allow ligation between the *Alu*I and *Hae*III sites. The ligated DNA (concatamers) was digested with *Bam*HI and *Eco*RI to produce a 0.5-kbp fragment having *Bam*HI and *Eco*RI sites at its ends. Equimolar amounts of a 4.3-kbp *Eco*RI-digested pBR322, which had been treated with alkaline phosphatase (BRL), the 1.2-kbp *Eco*RI-*Bam*HI fragment, the 0.3-kbp *Bam*HI-*Bam*HI fragment and the 0.5-kbp *Bam*HI-*Eco*RI fragment were ligated together. The ligated DNA was introduced into *Escherichia coli* HB101 cells and transformants carrying plasmids were grown in the presence of 25 μ g ml⁻¹ of ampicillin. Colonies which hybridized to mouse α -globin DNA were isolated and grown in L-broth to prepare plasmid DNA. The DNAs were characterized by mapping with restriction endonucleases *Pst*I, *Bam*HI and *Eco*RI (data not shown). Symbols: line, pBR 322; cross-hatched bar, α -globin mRNA coding sequences; stippled bar, noncoding sequences; V indicates deletion of 128 bp from the 3' terminus of the mouse α -globin DNA. **b**, Construction of pSNV-TK- α -globin $\Delta terR$ (RI): α -globin $\Delta terR$ DNA (100 μ g) was digested with *Eco*RI. A 2-kbp (*Eco*RI/*Eco*RI) α -globin-containing fragment from the digest was isolated after electrophoresis in a 1% agarose gel. pSNV-TK DNA (20 μ g) was digested with *Xba*I (New England Biolabs). The ends of these DNAs were filled in with T4 DNA polymerase (Bethesda Research Laboratories). The reaction mixture consisted of 330 μ M of dATP, dCTP, dGTP and dTTP, 167 μ g ml⁻¹ of bovine serum albumin, 16.6 mM of ammonium sulphate, 1 mM dithiothreitol, 6 mM MgCl₂, 50 mM Tris-HCl (pH 8.5), 5 μ g DNA fragment and 2 U of T4 DNA polymerase in 40 μ l. The reaction was carried out for 1 h at 37 °C. The reaction mixture was passed through a Sephadex G-50 column (0.7 \times 12 cm) to separate unreacted materials from DNA and the DNA was then precipitated with ethanol. Equimolar amounts of these DNA fragments were ligated together. The ligated DNA was introduced into *E. coli* HB101 cells and the transformants were grown in L-broth in the presence of 50 μ g ml⁻¹ ampicillin. Plasmids carrying α -globin $\Delta terR$ DNA were isolated from the transformants and the structures of the plasmid DNAs were characterized by mapping with restriction endonucleases (data not shown). Clones prepared in this manner with T4 DNA polymerase retain the cleavage sites of both *Xba*I and *Eco*RI. Construction of pSNV-TK- α -globin $\Delta terR$ (HinfI): α -globin $\Delta terR$ DNA was digested with *Hinf*I (New England Biolabs), which cuts 20 bp 3' to the sequences for the 5' end of globin mRNA, 118 bp 3' to the sequences for the carboxy-end of α -globin, and at two other sites in the 5'-noncoding region (see map in Fig. 3)¹¹. A DNA fragment of ~800 bp (*Hinf*I/*Hinf*I) containing α -globin sequences was isolated after electrophoresis in a 1% agarose gel. The ends of the *Hinf*I fragment were filled in by T4 DNA polymerase as described above. The filled-in DNA fragment and pSNV-TK that was digested with *Xba*I and had its ends filled in with T4 DNA polymerase were ligated together with T4 DNA ligase. Transformed *E. coli* HB101 cells carrying the plasmid were isolated and the plasmid DNA was mapped by restriction endonuclease digestion (data not shown). Cleavage sites of both *Xba*I and *Hinf*I were retained by this method of construction. Symbols: open bar, SNV; filled bar, herpes simplex thymidine kinase gene; other symbols as in Fig. 1a. (The sequences 3' of exon 3 are now shown cross-hatched to indicate the removal of the sequences for the 3' end of globin mRNA. The pBR322 sequences are not drawn to scale.)

to α -globin DNA (other hybridizing bands ran off the gel). The upper band contains the parental α -globin $\Delta terR$ coding sequences (A); the lower band contains 5' non-translated DNA sequences (B) and the progeny (smaller) α -globin $\Delta terR$ sequences (C). The increase in relative amount of the lower band locates the decreased size of the α -globin $\Delta terR$ DNA to the coding sequences.

Similar results were found after co-transfection with pSNV-TK- α -globin $\Delta terR$ (HinfI) and REV-A DNAs (data not shown).

To confirm the loss of intervening sequences in the progeny virus, molecular clones were made of the insert recovered from progeny virus. Closed circular viral DNA was prepared 3 days after infection of chicken cells with virus that was recovered 5 days after transfection with pSNV-TK- α -globin $\Delta terR$ (RI). This closed circular DNA was digested with *Xba*I and the α -globin $\Delta terR$ insert was cloned in the modified λ vector Charon 4A as described in Fig. 3 legend. Globin DNA-containing phage were then isolated and the inserts characterized by digestion with *Hinf*I and *Bam*HI. The results of restriction enzyme mapping are consistent with loss of the two intervening sequences in the α -globin DNA (Fig. 3). DNA sequencing then directly demonstrated that the two intervening sequences were precisely removed (data not shown).

To determine the rate of loss of intervening sequences in progeny virus, virus was collected 4–9 days after transfection and used to infect fresh chicken cells. Unintegrated linear viral DNA was then prepared 3 days after infection (7–12 days after transfection). Multiple cycles of infection had occurred in this time.

Fig. 2 Recovery of unintegrated viral DNA from chicken cells infected with recombinant virus. pSNV-TK- α -globin $\Delta terR$ (RI) DNA (10 μ g) and REV-A DNA (1 μ g) as helper were introduced into chicken fibroblastic cells in 100-mm Petri dishes in the presence of calcium phosphate. After 5 days, virus was collected from the medium and fresh chicken cells (30–100-mm Petri dishes) were infected with undiluted virus. Three days after infection, the cells were collected and unintegrated viral DNA was isolated by the Hirt procedure^{22,23}. The unintegrated viral DNA was digested with *Hinf*I, *Xba*I or *Eco*RI and analysed by electrophoresis in a 1.3% agarose gel. Each lane contained DNA from four Petri dishes. The gel was blotted onto nitrocellulose filter paper and the filter was hybridized with nick-translated ³²P-labelled globin-containing *Eco*RI fragment from α -globin $\Delta terR$ (RI). pSNV-TK- α -globin $\Delta terR$ (RI) DNA was used as a control (left two lanes). The maps of unintegrated viral DNA at the bottom represent the parental virus and progeny virus without globin intervening sequences. The smearing seen in the unintegrated viral DNA lanes is probably a result of degradation in cells killed by the virus infection²⁴. A distinct 0.56-kbp band is visible in the *Hinf*I lane of the original.

Fig. 3 Cloning and characterization of an α -globin DNA fragment from SNV-TK- α -globin $\Delta terR$ (RI). Isolation of circular unintegrated viral DNA from chicken cells infected with virus produced by chicken cells transfected with SNV-TK- α -globin $\Delta terR$ (RI) and REV-A DNAs: Virus-infected chicken cells (60–100-mm Petri dishes) were lysed with SDS 3 days after infection. Unintegrated viral DNA was isolated by the Hirt procedure. The Hirt supernatant fraction was treated with proteinase K (20 μ g ml⁻¹; Beckman) for 2 h at 37 °C and then with phenol and chloroform. One gramme of CsCl was added per ml of the preparation, and ethidium bromide was added to a final concentration of 0.1 mg ml⁻¹. The solution was centrifuged for 48 h in the Beckman 50 Ti rotor at 35,000 r.p.m. and 40 fractions were collected from the bottom of the centrifuge tube. 5 μ l of each fraction were spotted on to nitrocellulose filter paper, the DNA was denatured with 0.1 M NaOH and the filter was neutralized, heated at 80 °C for 2 h, and hybridized with ³²P- α -globin DNA. Fractions containing circular unintegrated viral DNA were collected and ethidium bromide and CsCl were removed by extraction with isopropanol and dialysis, respectively. The viral DNA was then digested with *Xba*I. Charon 4A DNA²⁵ was digested first with *Xba*I and then with alkaline phosphatase to remove terminal phosphate residues. Four molar equivalents of the insert DNA were added and the DNAs were ligated together. The ligated DNA was packaged, and the phage were used to infect *E. coli* DP50supF on NZYDT agar plates²⁵. The efficiency of isolation of positive plaques was about 10⁻³. The α -globin-containing phage were purified by serial dilution of the plaques containing the phage. DNA was extracted from purified phage, digested with *Xba*I and electrophoresed into a 1% agarose gel. The cleavage map of one of the clones is shown compared with the α -globin $\Delta terR$ DNA and the original α -globin gene¹¹. The thick vertical lines in exons 1 and 3 represent the ends of protein coding sequences. The numbers beneath the maps represent the sizes of the fragments found. Strategy used for sequencing the *Xba*I-digested globin DNA clone: the *Xba*I-digested DNA clone was digested with *Bam*HI followed by digestion with alkaline phosphatase. The DNA was labelled at its 5' ends with ³²P by T4 polynucleotide kinase (P-L Biochemicals) and then digested with *Hinf*I. DNA fragments of 300 and 260 bp were isolated and sequenced by the method of Maxam and Gilbert²⁶. The regions sequenced are indicated by arrows under the map of the cloned α -globin DNA and agree with the published sequence¹¹. IVS-1 is intervening sequence 1; IVS-2 is intervening sequence 2; 1 and 2 are the sequences of the regions corresponding to IVS-1 and IVS-2 after recovery from virus; cap is the 5' end of mouse α -globin mRNA; p(A) is the poly(A) addition site for mouse α -globin mRNA.

Figure 4 shows that virus with inserts containing intervening sequences was still present 7 days after transfection. Thus, the probability of losing the intervening sequences per replication cycle is less than 100%. However, by 9 days after transfection essentially all the viral DNA lacked the globin intervening sequences.

In a parallel experiment, virus was collected 4 days after transfection and passaged at 3-day intervals in fresh chicken cells. Before each passage, the unintegrated viral DNA was analysed as in the experiments described in Figs 2 and 4. Virus containing unspliced inserts was still detected after the first passage (7 days after the initial transfection) (data not shown). By the second passage all virus recovered contained only spliced globin DNA.

We believe that the loss of intervening sequences from these retroviral vectors occurred from genomic RNA for the following reason. In one of our constructions, pSNV-TK- α -globin $\Delta terR$ (HinfI), the *Hinf*I cleavage is ~20 bp 3' to the 5' end of sequences for globin mRNA¹¹ and so removes any promoter for globin mRNA synthesis. Progeny virus containing α -globin DNA without intervening sequences was recovered after transfection with pSNV-TK- α -globin $\Delta terR$ (HinfI) DNA (data not shown). Since no subgenomic RNA could be made, this finding indicates that splicing took place in genomic RNA rather than in globin mRNA followed by recombination with genomic RNA.

Fig. 4 Kinetics of loss of intervening sequences in recombinant virus. Virus produced by chicken cells transfected with pSNV-TK- α -globin Δ terR(R1) and REV-A DNAs was collected 4, 5, 6, 7, 8 and 9 days after transfection. Fresh chicken cells were infected with these viruses. Three days after infection (days 7–12 after transfection), unintegrated viral DNA was extracted by the procedure of Hirt^{22,23}. The DNAs were digested with *Eco*RI and analysed by electrophoresis in a 1.3% agarose gel. The gel was blotted onto a nitrocellulose filter and the filter was hybridized with nick-translated ³²P- α -globin DNA. Parallel preparations of DNA from uninfected chicken cells did not hybridize to mouse α -globin DNA (data not shown).

The difference between the normal 100% splicing of globin gene transcripts¹⁵ and the less efficient (~10%) splicing of the same sequences seen here may reflect the requirements of the retrovirus life cycle. Retroviruses normally synthesize some subgenomic mRNAs¹⁶. If all viral RNA were spliced, only subgenomic RNA and no progeny genomic RNA would be made. The retrovirus may therefore control the rate of splicing, perhaps through their 5' sequences which also control numerous other processes including encapsidation^{14,17,18}. Alternatively, the difference in cells or secondary structure of the RNA could be responsible for the difference in efficiency of splicing.

No virus containing DNA with one intervening sequence spliced out and the other remaining was found. Because the rate of loss of intervening sequences is less than 100%, this result indicates that loss of the two intervening sequences is not independent. Normal splicing of mouse β -globin mRNA precursor involves a partially spliced intermediate¹⁹.

The results reported here clearly demonstrate information transfer from DNA through spliced RNAs to DNA. They thus support the hypothesis that cDNA genes arose by reverse transcription of spliced RNA^{6–10,20}. However, it would not be correct to conclude that the results reported here indicate that retrovirus transfer is necessary for the formation of cDNA genes although it may well account for the origin of some viral oncogenes. In any case, our data illustrate how retroviruses can be used to delete intervening sequences from genomic DNAs, a process that would allow the expression of eukaryotic genes in prokaryotes.

We thank D. Hamer, NIH, for the α -globin plasmid, T. Schedl for help with cloning, I. Chen for advice, S. Watanabe for the DNA sequencing and our colleagues for helpful comments on the manuscript. This work was supported by NCI grants CA-07175 and CA122443. H.M.T. is an American Cancer Society Research Professor.

In *Bacillus subtilis*, DNA replication proceeds bidirectionally, commencing in the *Bam*HI fragment, B7 (see Fig. 4). The middle *Eco*RI fragment E19, generated from B7, is the first to be replicated, followed by the E22 fragment in one direction and by the E6' fragment in the other direction^{1,2}. The B7 fragment was also shown to inhibit the replication of a plasmid which carried this fragment^{3,4} and the minimal essential sequence for the inhibition (*sar*) was located to a 200-base pair (bp) region of E19, which contains two promoters, as deduced by the sequence analysis⁵. Previous studies showed that the E6' fragment was unique while E19 and E22 fragments hybridized to multiple sites on the chromosome. In addition, in the course of the analysis of an RNA covalently linked to DNA and synthesized at specific times related to chromosome initiation⁶, we found that this RNA was complementary both to the E19 and E22 fragments and to ribosomal RNA genes⁷. We show here that a ribosomal RNA gene set (*rrnO*) overlaps the first replicating fragments in one direction. The promoters for these genes are in fact the promoters of the *sar* sequence.

B. subtilis chromosomal DNA was digested to completion by *Bam*HI and *Sma*I restriction endonucleases, separated electrophoretically, and the resulting fragments were assayed by hybridization with ³²P-labelled E19 and E22. The patterns presented in Fig. 1 show that the E19 and E22 fragments hybridized with at least 7 different fragments on the chromosome, in agreement with earlier results⁴. A similar hybridization experiment was performed with the total chromosomal DNA using 16S and 23S RNA probes. The results presented in Fig. 2 showed that the E19 and E22 fragments hybridized with restriction fragments which are specific for the 16S RNA or for both 16S and 23S RNA. The bands corresponding to 14, 11 and 3.5 kbp *Bam*HI fragments, and to 7.2 and 5.4 kbp *Sma*I fragments, which are specific for the 23S RNA⁸, were absent in both E19 and E22 hybridization patterns.

To determine the precise homology between the E19 and E22 fragments and the ribosomal RNA genes, we took advan-

§ To whom correspondence should be addressed.

Fig. 1 Southern hybridization of E19 and E22 fragments with the *Bam*HI and *Sma*I *B. subtilis* DNA digests. Chromosomal DNA from *B. subtilis* 168 (*thy*, *trp*) was digested to completion either with *Bam*HI or with *Sma*I (New England Biolabs), electrophoresed in 0.7% agarose, transferred and fixed on nitrocellulose sheets (Millipore) according to the method of Southern¹⁹. DNA from plasmid pKY2700 containing E19 or E22 fragments⁴ was purified by caesium chloride-ethidium bromide equilibrium centrifugation followed by sedimentation on sucrose gradients and finally digested with *Eco*RI and electrophoresed in 1% agarose. After extraction from the gel, the E19 and E22 fragments were nick translated with [α -³²P]dCTP (400 Ci mmol⁻¹, Amersham France). Before mixing with ³²P-DNA the Southern transfers were incubated for 1 h at 65 °C in 0.02% Ficoll, 0.02% polyvinyl pyrrolidone, 0.02% bovine serum albumin, 100 μ g ml⁻¹ yeast tRNA 4 \times SSC. Then the ³²P-labelled E19 or E22 DNA was added and, after 18 h at 65 °C, the sheets were washed in 2 \times SSC, 0.5% SDS for 2 h at 65 °C, then for 1 h at 25 °C and finally in 2 \times SSC for 1 h at 25 °C. After washing the sheets were exposed to X-ray film.

tage of the restriction map of a ribosomal RNA gene set recently obtained by Bott *et al.*⁹. DNA from plasmid p14B1 containing the DNA sequence coding for one of the ribosomal RNA gene clusters, was completely digested as detailed in Fig. 3. The resulting fragments were separated electrophoretically and assayed by hybridization with ³²P-labelled E19 and E22 fragments. The E19 fragment showed homology with the fragment limited by the *Hind*III and *Eco*RI sites and containing the coding sequence for the 5'-terminus of 16S RNA (Fig. 3). The E22 fragment showed homology with the fragment limited by *Eco*RI sites and containing the coding sequence for the 3'-terminus of 16S RNA.

The restriction maps independently constructed by Bott *et al.*⁹ and Seiki *et al.*¹, for one of the ribosomal RNA gene clusters and the replication origin region respectively are remarkably similar, as shown in Fig. 4. Most of the differences could be explained by a small displacement of several of the sites. In fact, some heterogeneity has been observed in the organization of the different ribosomal RNA genes (ref. 10 and G. C. Stewart,

Fig. 2 Comparison of hybridization patterns obtained with ³²P-E19 and E22 fragments and ³²P-ribosomal RNA (16S+23S). E19 and E22 fragments were labelled with ³²P and hybridized with the *Bam*HI and *Sma*I *B. subtilis* DNA digests as described in Fig. 1 legend. The 16S and 23S ribosomal RNAs were purified from a nucleic acid extract by sedimentation through 15–30% sucrose gradients and labelled at their 5' termini with [α -³²P]ATP (3,000 Ci mmol⁻¹, Amersham France) and T4 polynucleotide kinase. The ³²P-labelled 16S and 23S were incubated with the Southern transfers for 18 h at 68 °C in 3 \times SSC and 0.1% SDS. After hybridization the sheets were washed in 3 \times SSC for 1 h at 37 °C, then in 3 \times SSC for 4 h at 48 °C. The sheets were exposed to X-ray film and the absorbance of the film image was measured using a densitometer (Kipp et Zonen). ³²P-E19 or ³²P-E22 fragments (—); ³²P-ribosomal RNA (16S+23S) (....).

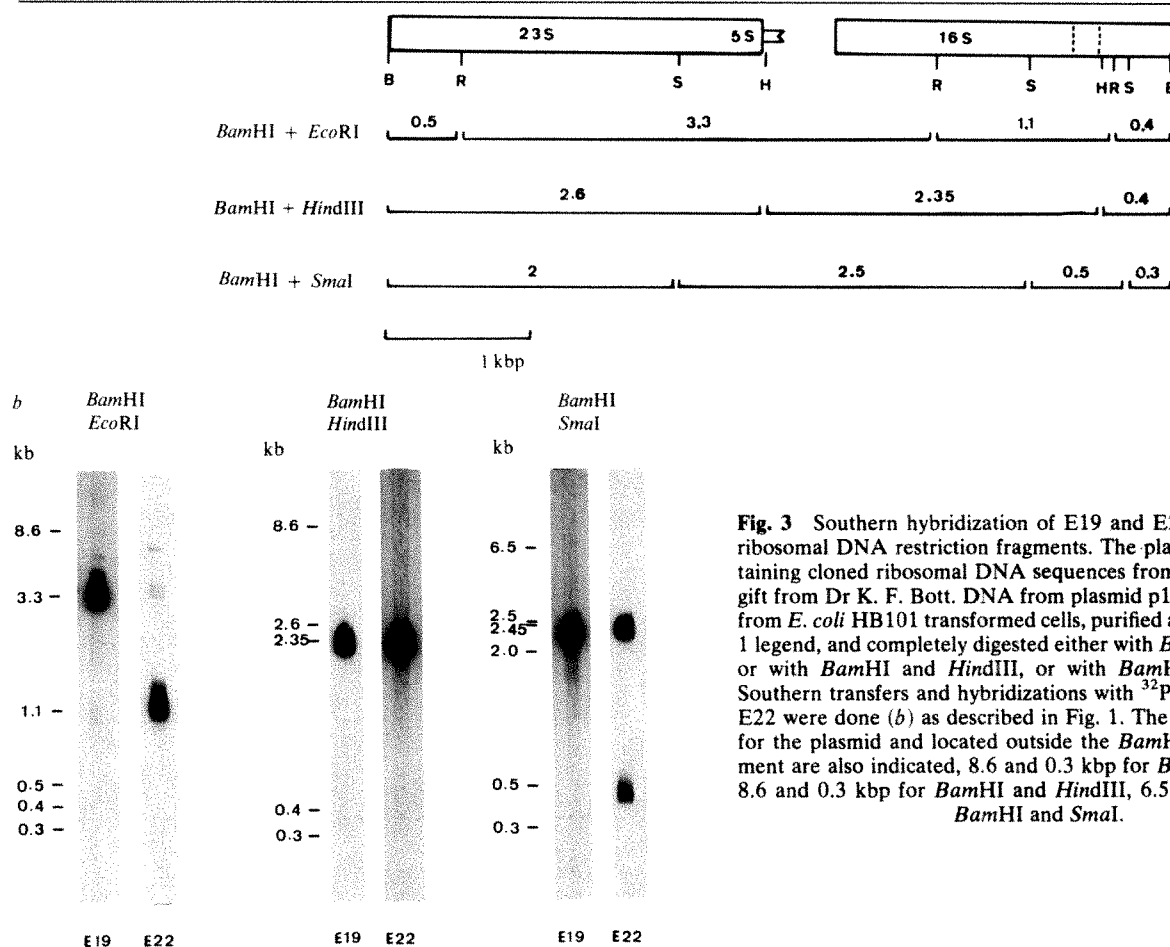

Fig. 3 Southern hybridization of E19 and E22 fragments with ribosomal DNA restriction fragments. The plasmid p14B1, containing cloned ribosomal DNA sequences from *B. subtilis*, was a gift from Dr K. F. Bott. DNA from plasmid p14B1 was prepared from *E. coli* HB101 transformed cells, purified as described in Fig. 1 legend, and completely digested either with *Bam*HI and *Eco*RI, or with *Bam*HI and *Hind*III, or with *Bam*HI and *Sma*I (a). Southern transfers and hybridizations with 32 P-labelled E19 and E22 were done (b) as described in Fig. 1. The fragments specific for the plasmid and located outside the *Bam*HI-generated fragment are also indicated, 8.6 and 0.3 kbp for *Bam*HI and *Eco*RI, 8.6 and 0.3 kbp for *Bam*HI and *Hind*III, 6.5 and 2.45 kbp for *Bam*HI and *Sma*I.

personal communication). Moreover, the similarity observed concerns not only the region covering the E19 and E22 fragments but also the region beyond the E22 fragment, suggesting the presence of a complete ribosomal RNA gene set in the region of the chromosome origin.

From the data obtained in this study, it seems likely that a 500-bp region, which has been shown to be responsible for the inhibitory effect on plasmid replication⁴, could include the ribosomal RNA promoters and a sequence of nucleotides which is normally removed from the precursor 16S RNA to form the mature molecule¹¹. Recently, the nucleotide sequence of this region has been determined and has revealed the presence of two tandem promoters located 98 bp apart⁵. The sequence of the analogous region of the ribosomal RNA genes cloned in p14B1 has been determined by K. F. Bott (personal communication). Comparison of the two regions shows two identical sequences of about 80 nucleotides located downstream from the second promoter, the second one coding for the 5' end of the mature 16S ribosomal RNA. These data strongly support

the homology reported here. Interestingly, there are some differences in the region of the second promoter and the sequence containing the first promoter is absent in the ribosomal RNA genes set cloned in p14B1.

Within the 500-bp region, the *sar* sequence (suppressor for autonomous replication) has been found to be essential for the *cis*-inhibition of plasmid replication⁵. This sequence contains the two promoters described above. The elimination of the second promoter dramatically affected both the inhibitory effect and *in vitro* transcription, suggesting that the transcriptional activity of the second promoter is involved in the *cis*-inhibition of DNA replication⁵. The location of the *sar* sequence very close to or overlapping the replication origin could explain the failure to isolate an autonomous replicative sequence from the *B. subtilis* chromosome. The *sar* sequence has been assumed to control negatively the initiation of the chromosome and this effect should be removed during initiation. It is of particular interest to note the isolation of an RNA covalently linked to DNA and synthesized at specific times related to

Fig. 4 Comparison of the restriction maps of the ribosomal RNA operon and the region of the replication origin. This figure also shows the location of the 500 bp sequenced segment of E19. P1 and P2 are the two promoters identified in the *sar* sequence. Data from Bott *et al.*⁹ and from Seiki *et al.*¹.

chromosome initiation⁹. Recently this RNA has been found to be homologous to the first replicating fragments E19 and E22 and thus appears as a possible candidate for the primer role at the replication origin (data not shown).

The chromosome replication origin has been located on the genetic map near *purA*, probably between *rec F15* and *ts8132* loci¹². A DNA-protein complex which is known to be related to the cells' ability to initiate chromosome replication has been located near the origin, on the B1 fragment contiguous to the B7 fragment^{13,14}. In addition, the *gua* gene has been found by transformation to be present in the B3 fragment, which is adjacent to B7 (data not shown). The identification of a ribosomal RNA sequence on the first replicating fragment E19 provides more precise information on the organization of the replication origin region. From the results presented here, it can be concluded that the region covered by the two promoters and the 16S RNA sequences must contain the origin or be located within a few hundred nucleotides of the origin.

The ribosomal RNA genes are probably present in 10 copies in *B. subtilis*^{8,10,15} and some of these genes have been mapped^{16,17}. This study reports the location of a new ribosomal

RNA gene set, which we call *rrnO*, close to the replication origin. The promoters and the leading sequence of the *rrnO* gene set may be unique and responsible for the specific properties associated with the replication origin of the chromosome. This is the first indication in prokaryotes that ribosomal RNA cistrons may be located at the replication origin. However, studies on eukaryotic chromosomes indicate that replication origins occur in each repeating unit of the ribosomal RNA clusters¹⁸.

A major question in understanding the regulation of DNA replication is how the number of chromosomes is maintained in the cell at a certain value, through successive generations and through changes in the environment that alter growth rate. The finding in *B. subtilis*, of a ribosomal gene set in the region of the replication origin may throw light on this question.

We thank Dr Kenneth F. Bott for his gift of plasmid p14B1, for communicating the sequence of the coding region for the 16S RNA and for helpful discussion. We also thank Dr I. Barry Holland for a critical reading of the manuscript. This work was supported by grants from the CNRS (L.A. 136) and from ATP Microbiologie.

Abnormal NAD⁺ levels in cells from patients with Fanconi's anaemia

Nathan A. Berger, Sosamma J. Berger & Donna M. Catino

Hematology/Oncology Division, Departments of Medicine and Pharmacology, The Jewish Hospital of St Louis, and Washington University School of Medicine, St Louis, Missouri 63110, USA

Poly(ADP-ribose) is synthesized from NAD⁺ in the nuclei of eukaryotic cells and the activity of the chromatin-bound enzyme, poly(ADP-ribose) polymerase, is markedly stimulated by DNA strand breaks^{1–7}. Recent studies suggest that poly(ADP-ribose) is associated with the repair of DNA damage^{8–10} and the process of cellular differentiation^{11,12}. Hence, abnormalities in the metabolism of poly(ADP-ribose) could be aetiologically related to some of the human genetic disorders of DNA repair, especially those that are characterized by congenital and developmental anomalies. Defects in poly(ADP-ribose) metabolism could arise from abnormalities in the enzyme poly(ADP-ribose) polymerase, abnormalities in levels of its substrate NAD⁺, the proteins that act as acceptors for poly(ADP-ribose) or polymer stability. We have examined cells from patients with genetic disorders of DNA repair to determine whether they contain the enzyme poly(ADP-ribose) polymerase, whether the enzyme increases its activity in response to DNA damage and whether the cells maintain normal levels of NAD⁺. We demonstrate here that cells from patients having Fanconi's anaemia have lower NAD⁺ levels than cells from normal donors. This abnormality may contribute to the disorders of DNA repair and congenital anomalies that characterize this disease^{13,14}.

Table 1 shows the NAD⁺ levels found in a series of normal and repair-deficient human skin fibroblasts. The normal cells maintained a mean NAD⁺ level of 1,140 ± 304 pmol per 10⁶ cells with a range from 870 to 1,570 pmol per 10⁶ cells. Cells from patients in two of the subgroups of xeroderma pigmen-

tosum maintained NAD⁺ levels that were slightly higher than normal. Cell lines from two patients with Cockayne's syndrome were examined; one had low and the other high NAD⁺ levels.

Cell lines derived from seven patients with Fanconi's anaemia (2061, 646, c111, 1196, c114, 368 and 1746) had low NAD⁺ levels compared with normal cells, while Fanconi's anaemia cell lines 2361, 369 and 449 maintained NAD⁺ levels that were in the low-normal range. The mean level of NAD⁺ in the Fanconi's fibroblasts was approximately half that of normal cells.

We then compared NAD⁺ levels in freshly prepared human lymphocytes derived from normal donors and from patients with Fanconi's anaemia. Normal human lymphocytes are resting intermitotic cells with low levels of pyridine nucleotides^{15,16}; when stimulated by phytohaemagglutinin (PHA), they undergo a marked expansion of their pyridine nucleotide pools, reaching peak levels on the third or fourth day of culture¹⁶. In the present study, NAD⁺ levels were measured in lymphocytes within 2–3 h of their preparation from fresh human blood and again after 3 days of PHA stimulation. Table 2 shows that the mean NAD⁺ level in resting lymphocytes from 35 normal donors was 80 ± 28 pmol per 10⁶ cells. Cells stimulated with PHA always showed marked increases in NAD⁺ levels, ranging from 3 to 16 times the NAD⁺ in resting cells.

Lymphocytes were prepared from five patients with Fanconi's anaemia and NAD⁺ levels were determined before and 3 days after PHA stimulation. Microscopic examination showed that the lymphocytes obtained from such patients underwent a normal agglutination reaction after PHA treatment. These cells also showed a normal increase in DNA synthesis as measured by ³H-thymidine (³H-TdR) incorporation on the third day after PHA stimulation. Initial NAD⁺ levels in freshly isolated lymphocytes from patients with Fanconi's anaemia were usually within the normal range. On PHA stimulation, the NAD⁺ levels increased; however, in the first four patients with Fanconi's anaemia, they were still below normal. Patient 4, whose PHA-stimulated lymphocytes exhibited an NAD⁺ level, at the lower limit of normal, was a 16-yr-old boy whose pancytopenia had partially responded to androgen therapy. Patient 5, who showed

Table 1 NAD⁺ levels (pmol per 10⁶ cells) in human fibroblasts

Normal cells		Xeroderma pigmentosum		Fanconi's anaemia	
Cell line	NAD ⁺	Cell line	NAD ⁺	Cell line	NAD ⁺
CRL1119	870 ± 247	CRL1223 (XPA)	2,210 ± 981	GM2061	245 ± 122
325	914 ± 281	CRL1160 (XPD)	1,470 ± 741	GM0646	286 ± 196
CRL1141	983 ± 217	Mean	= 1,840 ± 522	c111	398 ± 179
CRL1220	1,010 ± 361	Cockayne's syndrome		CRL1196	453 ± 107
CRL1121	1,480 ± 691	Cell line	NAD ⁺	c114	512 ± 533
AG1518	1,570 ± 458			GM0368	699 ± 440

				GM2361	892 ± 540
		GM0739	684 ± 363	GM0369	907 ± 214
		GM1856	2,290 ± 4	GM0449	973 ± 454
		Mean	= 1,490 ± 1,140	Mean	= 614 ± 239

The sources of the human skin fibroblasts were as follows: AG1518, GM0739, GM1856, GM2061, GM0646, GM0368, GM1746, GM2361, GM0369 and GM0449 were all from the Human Genetic Mutant Cell Repository, Camden, New Jersey. CRL1119, CRL1141, CRL1220, CRL1121, CRL1223, CRL1160 and CRL1196 were from the American Type Culture Collection, Rockville, Maryland. Cell lines c111 and c114 were from Dr M. Swift, University of North Carolina. Cell line 325, from a patient with β -glucuronidase deficiency, was obtained from Dr W. Sly, Washington University Medical School. As these cells have no known disorder of DNA repair they are included in this series with the normal cell lines. All lines were maintained in alpha modified Eagle's medium supplemented with 20% heat-inactivated fetal calf serum (FCS) 100 U ml⁻¹ penicillin, 100 μ g ml⁻¹ streptomycin and 25 mM HEPES, pH 7.2 at 37 °C. All studies were performed with three batches of FCS, both normal and abnormal cells were processed with each batch of serum and results were independent of the batch used. Most of the cell lines were examined for mycoplasma by independent assays at Flow Laboratories and all those examined were found to be free of contamination. For NAD⁺ determinations, confluent cultures in T75 flasks were split 1:3 into 100-mm Petri dishes with 15 ml medium and incubated at 37 °C. NAD⁺ assays were performed on the second day after plating. Cells were quickly scraped from plates, suspended in their growth medium by vortexing and the cell samples were processed for NAD determination by extraction and enzymatic cycling techniques as described previously^{16,24}. Additional samples of cell suspension were diluted into 5% Cetrimide and cell numbers counted electronically on a Coulter counter model F. All assays were performed in duplicate on duplicate samples taken at each time point. All assays were therefore performed in quadruplicate with less than 10% variation between separate assays. Results for each cell line are presented as the mean \pm s.d. for assays performed at multiple passages between 7 and 20 except for cell lines CRL1220 and CRL1121 which were studied between passages 19 and 24. Differences between NAD⁺ values in normal and Fanconi's anaemia cells are significant at $P < 0.01$.

a completely normal increase in NAD⁺ in response to PHA, was a 20-yr-old woman whose pancytopenia was in a spontaneous partial remission. The mean NAD⁺ level in PHA-stimulated lymphocytes from all patients with Fanconi's anaemia was approximately half that detected in normal cells.

Table 2 NAD⁺ levels (pmol per 10⁶ cells) in human lymphocytes

Normal donors	Control	PHA

1	59	176
2	27	66
	71	191
3	59	99
	74	244
4	39	252
5	98	693
Mean	61 ± 23	245 ± 208

Peripheral blood lymphocytes were prepared on Ficoll-Hypaque gradients as described previously^{16,17} from fasting normal donors and patients with Fanconi's anaemia. None of these donors were the same as those used in Table 1. The cells were diluted into alpha modified Eagle's medium supplemented with 2 mM glutamine, 100 U ml⁻¹ penicillin, 100 μ g ml⁻¹ streptomycin, 10% heat-inactivated FCS and 25 mM HEPES, pH 7.2. For PHA studies, cells were incubated at 3×10^5 cells ml⁻¹ in a 20 ml T flask at 37 °C with 2 μ g ml⁻¹ sterile L-phytohaemagglutinin (Sigma). Control values were determined within 2–3 h of the time that cells were isolated from peripheral blood; PHA-stimulated values were determined after 3 days' incubation at 37 °C. At each time point cells were collected for NAD extraction and determination by enzymatic cycling assays as previously described^{16,24}. Additional samples were diluted into 5% Cetrimide for cell counting. All assays were performed in duplicate on duplicate samples taken at each time point; values shown are the means of assays performed in quadruplicate, with less than 10% variation between replicate assays. The five patients were all diagnosed as having Fanconi's anaemia (FA) based on pancytopenia, chromosomal abnormalities, typical skin changes, retarded growth and congenital anomalies of kidneys and bones. Their ages and sexes are as follows: 1, 10 yr (F); 2, 9 yr (F); 3, 11 yr (F); 4, 16 yr (M); 5, 20 yr (F). Patients 2 and 3 are sisters; cells from each of these two patients were examined on two separate occasions. Patient 4 was taking 2.5 mg oxymethalone every other day. The other patients were not receiving any drugs. Cells from 35 normal donors were used to establish the NAD⁺ level in control lymphocytes and cells from 25 of these donors were stimulated with PHA to determine the NAD⁺ levels in PHA-stimulated cells. There was no significant difference in NAD⁺ levels in resting lymphocytes between normal donors and patients with Fanconi's anaemia. The difference in NAD⁺ levels in PHA-stimulated cells between normal and Fanconi's anaemia patients was significant at $P < 0.01$.

As the highest NAD⁺ levels in the mitogen-stimulated lymphocytes from Fanconi's anaemia patients occurred in those two whose diseases were in partial remission, it is possible that their defect in maintaining NAD⁺ levels was improved. Alternatively, it is possible that the ability to achieve normal NAD⁺ levels contributes to the attainment of remission.

Additional studies were performed in which lymphocytes from normal donors were mixed with cells from patients with Fanconi's anaemia before extraction and measurement of NAD⁺ levels. The cells from patients with Fanconi's anaemia contained no substances that interfered with either the extraction or the measurement of NAD⁺. Furthermore, when lymphocytes from normal donors were co-cultivated with lymphocytes from Fanconi's anaemia patients, the final NAD⁺ values were those expected from the sum of the cells grown independently. Thus, Fanconi's anaemia cells contain no factors capable of reducing NAD⁺ levels in normal cells in the same culture system. Furthermore, the presence of normal cells does not correct the decreased NAD⁺ levels in the Fanconi's anaemia cells.

Freshly prepared human lymphocytes were also used to assay for the presence of poly(ADP-ribose) polymerase in Fanconi's anaemia and to determine whether its activity increased in a normal manner in response to DNA damage¹⁷. These studies were performed in lymphocytes that were untreated (control cells), or treated either with UV irradiation (50 J m⁻²) or with *N*-methyl-*N'*-nitro-*N*-nitrosoguanidine (MNNG; 20 μ g ml⁻¹), incubated for 3 h at 37 °C, then permeabilized and supplied with ³H-NAD to measure the activity of poly(ADP-ribose) polymerase¹⁷. Table 3 shows that the enzyme was present and its activity increased in normal cells in response to treatment with UV irradiation or MNNG. Similarly, it was present in cells from patients with Fanconi's anaemia and its activity increased in response to UV irradiation and treatment with MNNG. While the latter cells showed less enzyme activity than the normal cells, they nevertheless did respond to DNA damage as did normal cells with an increase in activity of poly(ADP-ribose) polymerase.

As a result of the increase in poly(ADP-ribose) polymerase activity that occurs in response to DNA damage, cellular pools

Table 3 Poly(ADP-ribose) synthesis (pmol per 10^6 cells per 30 min) in DNA-damaged lymphocytes

	Normal donors	Donors with Fanconi's anaemia
Control	36 ± 18 (n = 15)	17 ± 4 (n = 2)
UV-irradiated (50 J m ⁻²)	179 ± 70 (n = 12)	90 ± 0 (n = 2)
MNNG (20 µg ml ⁻¹)	511 ± 235 (n = 5)	260 ± 171 (n = 2)

Immediately after preparation of peripheral blood lymphocytes from normal donors or patients with Fanconi's anaemia, the cells were suspended at 3×10^5 ml⁻¹ in the same medium as described in Table 2. Control cells received no further treatment. UV-irradiated cells received 50 J m⁻² as previously described¹⁷ and MNNG-treated cells were adjusted to contain final concentrations of 20 µg ml⁻¹ MNNG and 0.2% dimethyl sulphoxide (DMSO). Previous studies have shown that mock-irradiation or DMSO treatment has no effect on poly(ADP-ribose) synthesis²⁰. Cells were incubated in tissue culture medium at 37 °C for 3 h, then permeabilized; 10^6 cells were then incubated with ³H-NAD (NEN) for 30 min and treated with 20% cold trichloroacetic acid to measure incorporation into poly(ADP-ribose) as described previously¹⁷. The result for each donor is the mean of assays performed in triplicate which agreed within 10%. The results for normal cells are expressed as the mean ± s.d. of assays performed on cells from the number of donors is indicated in parentheses. The values for the patients with Fanconi's anaemia were obtained for lymphocytes from two donors, patients 1 and 5 in Table 2.

of NAD⁺ can be rapidly consumed¹⁸⁻²¹. Table 4 shows that NAD⁺ levels decreased in normal and Fanconi's anaemia cells after UV irradiation and treatment with MNNG. This fall in NAD⁺ levels serves as an independent demonstration that DNA damage activates poly(ADP-ribose) polymerase in Fanconi's anaemia cells as it does in normal cells^{20,21}. Although these determinations were only performed on cells from two donors, it is interesting that the residual NAD⁺ levels in Fanconi's anaemia cells were lower than in normal cells. These exceptionally low NAD⁺ levels may severely impair the ability of Fanconi's anaemia cells to maintain their energy metabolism during the period required for the normal DNA repair processes. For example, when the NAD⁺ levels of L1210 and 3T3 cells are depleted by growth in nicotinamide-deficient medium, they lose their ability to perform unscheduled DNA synthesis and to reseat DNA strand breaks^{8,9}. Thus, the low NAD⁺ levels in cells from some patients with Fanconi's anaemia may contribute to their decreased ability to recover from DNA damage.

Many studies have identified NAD⁺ levels and poly(ADP-ribose) synthesis as important factors in the normal process of differentiation. Nicotinamide analogues that interfere with NAD⁺ synthesis prevent normal differentiation and result in congenital anomalies in developing embryos²². Incubation of chick mesenchymal cells in high levels of nicotinamide induce high intracellular NAD⁺ levels and cause cells to differentiate into myoblasts, whereas incubation in medium with low nicotinamide result in NAD⁺-depleted cells and cause differentiation into cartilage cells¹¹. Poly(ADP-ribose) polymerase activity increases when myoblasts differentiate into myotubes and when Friend erythroleukaemic cells are induced to synthesize haemoglobin^{12,23}. Thus, the pleiotropic abnormalities that occur in patients with Fanconi's anaemia may be explained by abnormalities in the sizes of their NAD⁺ pools.

More studies are clearly required to determine whether decreased NAD⁺ pools in patients with Fanconi's anaemia are due to underproduction or over-utilization. In addition, it will

Table 4 NAD⁺ levels (pmol per 10^6 cells) in DNA-damaged lymphocytes

	Normal donors	Donors with Fanconi's anaemia
Control	79 ± 20 (n = 19)	80 ± 28 (n = 2)
UV-irradiated (50 J m ⁻²)	11 ± 7 (n = 15)	0.7 ± 0.1 (n = 2)
MNNG (20 µg ml ⁻¹)	6 ± 7 (n = 6)	0.4 ± 0.5 (n = 2)

Control and DNA-damaged cells were treated as described in Table 3 then incubated in tissue culture medium at 37 °C for 3 h. Cells were collected for NAD assays and cell counts as described in Table 2. The values represent the mean ± s.d. of assays performed on cells from the number of donors given in parentheses. The assays using cells from patients with Fanconi's anaemia were performed on lymphocytes from two donors, patients 1 and 5 in Table 2.

be necessary to determine whether the low NAD⁺ levels are the cause or consequence of the DNA repair defect. Finally, longitudinal studies will be required to investigate the relationship of NAD⁺ levels to the severity of the disease and the possibility that some of the abnormalities may be ameliorated by correcting NAD⁺ levels.

This work was supported by NIH grant GM26463 and American Cancer Society grants CH134 and BC4W. Some of the cell culture media used in these experiments were prepared in a Cancer Center Facility funded by the NCI. N.A.B. is a Leukemia Society of America Scholar. We thank Drs W. Sly and M. Swift for cell cultures, and Drs G. Broun, V. Land and H. Zarkowsky for allowing us to study their patients.

Sulphation of tyrosine residues—a widespread modification of proteins

Wieland B. Huttner

Department of Neurochemistry, Max-Planck-Institute for Psychiatry, D-8033 Martinsried/Munich, FRG

Of the many known covalent modifications of proteins¹, few have been recognized as widespread. Among these modifications, protein phosphorylation has been extensively studied²⁻⁴. Recently, phosphorylation of tyrosine residues has been implicated in regulatory events such as cell transformation and hormone-induced cell growth⁵⁻⁷. The present study explores the possibility that another modification of tyrosine residues in proteins, tyrosine sulphation, may be widespread. This modification is particularly interesting because of the molecular resemblance of tyrosine-O-sulphate and tyrosine-O-phosphate. Protein sulphation on tyrosine residues was found to occur in all cell types in culture and all tissues *in situ* so far examined. Moreover, for each cell type and tissue, proteins containing tyrosine-O-sulphate were found in distinct electrophoretic patterns throughout the molecular weight range studied. Thus, protein sulphation on tyrosine residues appears to be a widespread covalent modification, and may have an important role in cell function.

Protein sulphation on tyrosine residues was studied in the following cells in culture: bovine adrenal cells, chicken embryo fibroblasts, chicken embryo muscle cells, chicken embryo retina cells, rat brain cells and rat pheochromocytoma cells. Cell cultures were incubated with either ³⁵S-sulphate or ³⁵S-sulphate plus ³H-tyrosine (see Fig. 1 legend for experimental details).

Cellular proteins were then separated by SDS-polyacrylamide gel electrophoresis. The gels were divided from the top to the dye front into 10 equal portions containing the cellular proteins of high molecular weight to low molecular weight, respectively. Proteins from the individual gel pieces were hydrolysed, and the hydrolysates were analysed for radioactive tyrosine-*O*-sulphate by thin-layer electrophoresis at pH 3.5 followed by autoradiography. A typical autoradiogram of ^{35}S -labelled material obtained from one of the gel pieces is shown in Fig. 1c. The following lines of evidence, taken together, indicate that the radioactive substance migrating towards the anode on electrophoresis at pH 3.5 was indeed tyrosine-*O*-sulphate. (1) The radioactive substance migrated exactly as authentic tyrosine-*O*-sulphate⁸ in this one-dimensional separation (Fig. 1c) and on two-dimensional electrophoresis at pH 1.9 and pH 3.5. The migration of the radioactive substance was clearly different from that of methionine and cysteine (neither of which migrated towards the anode at pH 3.5) and from that of cystic acid (which migrated ~1.5 times faster towards the anode than tyrosine-*O*-sulphate). (2) The radioactive substance appeared to be an amino acid since it could also be generated by extensive pronase digestion alone. (3) The radioactive substance appeared to have the same pH-stability⁹ as authentic tyrosine-*O*-sulphate since the sulphate group was not removed by alkali treatment but was removed by treatment with 1 M HCl for 5 min at 100 °C. (4) The radioactive substance, when obtained from double-labelled cells, contained both ^{35}S -sulphate and ^3H -tyrosine (Fig. 1a).

The radioactivity in the tyrosine-*O*-sulphate spot obtained after thin-layer electrophoresis of the protein hydrolysates was quantitated for all 10 gel pieces of each cell type studied in culture. The electrophoretic patterns of protein-incorporated radioactive tyrosine-*O*-sulphate thus obtained are illustrated in Fig. 1 for chicken embryo fibroblasts (CEF, panel a) and rat pheochromocytoma cells (PC-12, panel b). For both CEF and PC-12 cells, proteins that had incorporated ^{35}S -sulphate on tyrosine residues were found in all gel pieces, that is throughout the molecular weight range studied. However, the electrophoretic pattern of protein-incorporated ^{35}S -tyrosine-*O*-sulphate observed for CEF (Fig. 1a, solid line) was clearly different from that observed for PC-12 cells (Fig. 1b, solid line). Since the CEF proteins had been double-labelled with both ^{35}S -sulphate and ^3H -tyrosine, it was also possible to analyse the sulphation of tyrosine residues by counting the tyrosine-*O*-sulphate spot for ^3H -label present on the benzene ring of tyrosine. The electrophoretic pattern of protein-incorporated ^3H -tyrosine-labelled tyrosine-*O*-sulphate (Fig. 1a, dashed line) was found to be almost identical to that of ^{35}S -sulphate-labelled tyrosine-*O*-sulphate (Fig. 1a, solid line). Using the experimental approach illustrated in Fig. 1, the other cell types studied in culture (adrenal, brain, muscle and retina cells) also gave distinct electrophoretic patterns of cellular proteins containing tyrosine-*O*-sulphate throughout the molecular weight range studied.

In the analysis of PC-12 cells (Fig. 1b), the 120K-80K molecular weight region of the gel (indicated in Fig. 1b by the

Fig. 1 Protein sulphation on tyrosine residues in chicken embryo fibroblasts (CEF) and rat pheochromocytoma cells (PC-12) in culture. Cells were incubated for 18 h in sulphate-free Dulbecco's modified Eagle's medium (DMEM) containing 0.3 mCi ml^{-1} of ^{35}S -sulphate and, in the case of CEF, $25 \mu\text{Ci ml}^{-1}$ of L-[3, 5- ^3H]tyrosine. (The concentration of 'cold' sulphate in normal DMEM was sufficient to reduce radioactive sulphate incorporation markedly.) The medium was then removed, the cells were solubilized in Laemmli sample buffer¹⁶, and cellular proteins separated on a 7.5% SDS-polyacrylamide gel. The gel was fixed in 50% methanol/10% acetic acid, stained with Coomassie blue, and dried. Each lane of the dried gel, containing either CEF or PC-12 cell proteins, was then cut from the top to the dye front into 10 equal portions representing different molecular weight regions. The individual gel pieces were reswollen in 50 mM ammonium bicarbonate containing $100 \mu\text{g ml}^{-1}$ of pronase and incubated for 24 h at 37 °C. The eluates were lyophilized, dissolved in 0.2 M barium hydroxide, evacuated, incubated for 24 h at 110 °C, neutralized with sulphuric acid, and centrifuged. The supernatants were lyophilized, dissolved in a solution containing $5 \mu\text{g}$ of tyrosine-*O*-sulphate standard⁸, spotted on TLC-cellulose sheets, and subjected to electrophoresis in 5% acetic acid/0.5% pyridine, pH 3.5. Panel c shows a typical autoradiogram after thin-layer electrophoresis of ^{35}S -labelled material obtained from one of the gel pieces. The dashed line indicates the position of the tyrosine-*O*-sulphate standard, detected by ninhydrin staining. For each of the 10 gel pieces of CEF (panel a) and PC-12 cells (panel b), the radioactivity in the tyrosine-*O*-sulphate spot was determined by liquid scintillation counting and is expressed as per cent of that obtained from the gel piece giving the maximum value (100%): ^{35}S (solid lines) CEF 3,925 c.p.m., PC-12 cells 2,405 c.p.m.; ^3H (dashed line) CEF 294 c.p.m. Values are from left to right for gel pieces containing high molecular weight proteins to gel pieces containing low molecular weight proteins. Arrows indicate the positions of molecular weight marker proteins. The solid bar on the abscissa of panel b indicates the region of the gel that was subjected to peptide mapping after limited proteolysis¹⁰ ($1.5 \mu\text{g}$ of *Staphylococcus aureus* V8 protease) with the modifications described elsewhere¹⁶. Panel d shows an autoradiogram of the proteolysis gel.

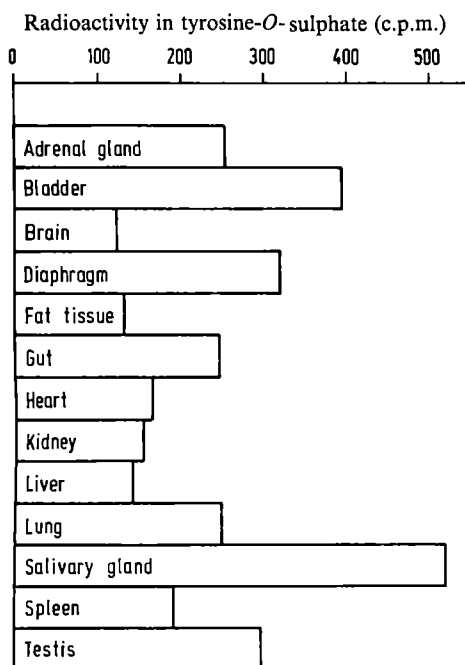

Fig. 2 Protein sulphation on tyrosine residues in various rat tissues *in situ*. At 18 h after an intraperitoneal injection of 20 mCi of ^{35}S -sulphate, rat tissues were freed of blood by perfusion with saline and were then rapidly homogenized in 3% SDS. Aliquots of each tissue containing equal amounts of protein (300 μg) were subjected to SDS-polyacrylamide gel electrophoresis and analysed for protein-incorporated ^{35}S -tyrosine-*O*-sulphate as described in Fig. 1 legend. The radioactivity in tyrosine-*O*-sulphate is given for tissue proteins from a whole lane of the gel.

solid bar) contained the highest amounts of protein-incorporated ^{35}S -tyrosine-*O*-sulphate. The same region of a duplicate gel was subjected to limited proteolysis¹⁰ during a second SDS-polyacrylamide gel electrophoresis step. Subsequent autoradiography of the proteolysis gel showed that the proteins from the 120K–80K region yielded two distinct patterns of ^{35}S -labelled fragments (Fig. 1*d*). Extensive pronase treatment of individual gel pieces containing these fragments yielded ^{35}S -tyrosine-*O*-sulphate in each case.

Since sulphation of proteins on tyrosine residues occurred in a variety of cell types in culture, it was of interest to determine whether this modification could also be observed after *in vivo*-labelling of tissues *in situ*. For this analysis (see Figs 2 and 3 legends for experimental details), 20 tissues were dissected from a rat 18 h after the animal had been injected intraperitoneally with inorganic ^{35}S -sulphate. With a single injection of 20 mCi of inorganic ^{35}S -sulphate into a 150 g rat, one would expect a marked dilution of the radioactive label and a great reduction in its specific activity because of the presence of endogenous inorganic sulphate in the body fluids. Nevertheless, radioactive sulphate incorporation into proteins on tyrosine residues could be detected in all 20 rat tissues examined. The results for 13 tissues are given in Fig. 2.

In addition, the electrophoretic pattern of proteins containing ^{35}S -tyrosine-*O*-sulphate was also determined for each tissue, using the experimental approach described above for cultured cells. These results are illustrated in Fig. 3 for three of the tissues examined, adrenal gland, gut and lung. These three tissues contained similar amounts of the total protein-incorporated ^{35}S -tyrosine-*O*-sulphate. However, the electrophoretic patterns of tissue proteins containing ^{35}S -tyrosine-*O*-sulphate were distinct for the three tissues. In fact, all the other tissues examined also gave distinct electrophoretic patterns of proteins containing ^{35}S -tyrosine-*O*-sulphate throughout the molecular weight range studied.

Only one protein, fibrinogen⁹, and a few biological peptides^{11–15} have so far been demonstrated to contain tyrosine-*O*-sulphate. The results of this study provide evidence that in all

cell types in culture and all tissues *in situ* so far examined, many proteins are sulphated on tyrosine residues. Two observations could help to explain why this widespread occurrence of protein sulphation on tyrosine residues has not been reported so far. First, the ester bond of tyrosine-*O*-sulphate is remarkably acid-labile⁹. The sulphate group is therefore likely to be hydrolysed in some of the common protein-chemical procedures. Second, ^{35}S -sulphation of proteins and other macromolecules on carbohydrate moieties tends to obscure the presence of proteins containing ^{35}S -tyrosine-*O*-sulphate, for example on autoradiography of SDS-polyacrylamide gels.

The widespread occurrence of protein sulphation on tyrosine residues suggests that this modification may have an important role in cell function. The distinct electrophoretic patterns of proteins containing tyrosine-*O*-sulphate that were observed in many different cell types raise the possibility that protein sulphation on tyrosine residues may be involved in a variety of cellular processes.

If protein sulphation on tyrosine is found to occur in the same subcellular compartment as phosphorylation on tyrosine, then the possibility should be considered that tyrosine residues which are physiologically *O*-sulphated may be subject to 'false' modification by becoming *O*-phosphorylated (and vice versa). Such false modification may have significant biological consequences. The false modification of tyrosine residues may not be fully recognized as such by the cell, since there is a molecular resemblance of tyrosine-*O*-sulphate and tyrosine-*O*-phosphate. The false modification of tyrosine residues may, however, be dissimilar enough from the physiological modification to perturb the balance of cellular regulation.

Fig. 3 Electrophoretic patterns of proteins containing tyrosine-*O*-sulphate in rat adrenal gland, gut and lung. The tissues were labelled *in situ* with ^{35}S -sulphate and tissue proteins were subsequently solubilized as described in the legend to Fig. 2. Aliquots containing equal amounts of proteins (3 mg) were subjected in duplicate to SDS-polyacrylamide gel electrophoresis on either 7.5% or 15% gels. Each of the gels was cut into five portions, representing different molecular weight ranges as indicated on the abscissa. Gel pieces containing molecular weight ranges above 60,000 were obtained from the 7.5% gels, the other gel pieces were obtained from the 15% gels. Analysis of individual gel pieces for protein-incorporated ^{35}S -tyrosine-*O*-sulphate was performed as described in the legend to Fig. 1. Maximum values (100%) were: adrenal gland 583 c.p.m., gut 477 c.p.m., lung 616 c.p.m.

I thank Professor H. Thoenen for his continuous support and advice, Dr K. von der Helm for donating CEF cells, H. Thorun for PC-12 cells, C. Suchanek for technical assistance, and Dr L. DeGennaro, Professor G. Gerisch, Professor D. Oesterhelt and my colleagues Dr R. Lee and Dr S. Por for their helpful comments on the manuscript.

Diversity of cholesterol exchange explained by dissolution into water

Eigil Bojesen

Institute of Experimental Hormone Research, University of Copenhagen, 71 Nørre Alle, DK-2100 Copenhagen, Denmark

It is usually considered that the stability of lipid bilayers results from the elastic resistance of water to the dissolution of hydrophobic compounds^{1,2}. However, attempts to describe this unique property of water in more detail^{2,3} have been difficult and some authors⁴⁻⁷ believe that the dispersion attraction of apolar molecules (London-van der Waals forces) is the most important factor. Details of the transfer kinetics into water of apolar compounds may elucidate this. Here I describe an analysis of the kinetics of cholesterol exchange between erythrocytes and lipoproteins that makes it possible to calculate precisely the widely differing specific rate constants of cholesterol dissolution from both kinds of structures. The analysis also accounts qualitatively for the different exchange kinetics reported for homologous and heterologous dispersed systems in water.

The fairly rapid exchange of cholesterol between erythrocytes and lipoproteins⁸ was originally assumed to reflect the dissolution of cholesterol from both dispersed phases. However, this has been questioned as the rate of exchange in this and other heterologous binary systems depends on the concentrations of the lipid particles⁹⁻¹², suggesting a collision frequency limitation, and transfer during collision. However the surfaces of lipoproteins and erythrocytes in rats are, on average, more than 100 Å apart¹³, closer contact being prevented by the cell glycocalyx. Furthermore, the kinetics of cholesterol exchange in pure homologous binary systems of artificial lipid vesicles is incompatible with a collision limitation¹⁴⁻¹⁶. The problem remains of why the kinetics are so different in heterologous and homologous systems.

Consider a closed system containing the amounts *A* and *B* of cholesterol in two dispersed lipid phases in equilibrium. If the exchange of cholesterol between the two phases is mediated solely by the amount, *C*, of cholesterol in water the scheme of equilibrium becomes:

In a homologous system *A* and *B* could be present in two separable types of liposomes and in a heterologous system, such as erythrocytes in serum, they represent the cholesterol of the cell membranes and in the lipoproteins, respectively.

In the tracer experiments in which *A* or *B* is labelled initially, the most simple corresponding scheme for the time-dependent amounts of *a*, *b* and *c* of tracer is

In this scheme it is assumed that only one pair of rate constants describes the transfer of the tracer in and out of each of the dispersed phases. As *c* is very small compared with *a* and *b* the scheme describes an experiment with monophasic exchange kinetics eventually leading to isotopic equilibrium. As such it does not differ from a simple two pool model, but whereas the two pool model is only a mathematical concept, the above scheme includes rate constants of real physical significance. As the processes are slow compared with diffusion equilibria within distances of ~100 Å, the tracer is evenly distributed in the aqueous phase with the concentration *c_w*. If *α* and *β* represent the reactive surface areas of the two kinds of dispersed phases the system approaches tracer equilibrium according to the two rate equations

$$-da/dt = k_1a - k_2c_w\alpha \quad (1)$$

$$-db/dt = k_3b - k_4c_w\beta \quad (2)$$

Thus *k₁* and *k₃* are first order whereas *k₂* and *k₄* are second order rate constants.

By eliminating *c_w* and using the substitution

$$Q = \frac{k_2\alpha}{k_4\beta}$$

we get

$$da/dt + k_1a = Q(db/dt + k_3b) \quad (3)$$

At equilibrium, when *t* → ∞, the ratio *a_∞/b_∞* is determined by

$$\frac{a_\infty}{b_\infty} = Q \frac{k_3}{k_1} = f_\infty \quad (4)$$

The low water solubility of cholesterol¹⁷ means that the total amount of tracer, *R*, in the system is equal to (*a* + *b*) and that *da/dt* = -*db/dt*.

Thus one of the two variables in (3) can be eliminated. Written in terms of *a* we get

$$da/dt + k_1a = -Qda/dt + k_3QR - k_3Qa \quad (5)$$

As *Q* and *R* are time-independent this equation can be solved by separation of the variables; followed by integration between the limits of *t* from 0 to *t* and of *a* from *a₀* to *a_t*. Using the identities (*R* - *a₀*) = *b₀*, (*R* - *a_t*) = *b_t*, and *Q* = *f_∞*(*k₁/k₃*), we get

$$\ln \left[\frac{a_t - f_\infty b_t}{a_0 - f_\infty b_0} \right] = -t \left[\frac{k_1(1 + f_\infty)}{1 + (k_1/k_3)f_\infty} \right] \quad (6)$$

This equation defines a rate constant *ε*

$$\epsilon = \frac{k_1(1 + f_\infty)}{1 + (k_1/k_3)f_\infty} \quad (7)$$

Table 1 The specific rate constants of cholesterol dissolution from red cells and lipoproteins

Type of experiment	No. of experiments	Correlation coefficient	<i>k₃</i> (h ⁻¹) (mean ± s.e.m.)	<i>k₁</i> (h ⁻¹) (mean ± s.e.m.)
Cell → Serum	18	0.988	3.10 ± 0.12	0.224 ± 0.012
Serum → Cell	24	0.985	3.30 ± 0.12	0.203 ± 0.007
Both types, all <i>F</i>	42	0.986	3.21 ± 0.087	0.211 ± 0.006
Both types (1.15 < <i>F</i> < 5.8)	25	0.70	2.82 ± 0.61	0.225 ± 0.014

k₁ and *k₃* are the rate constants for dissolution of cholesterol from red cells and from lipoprotein, respectively, calculated on the basis of the linear regression (1 + *F*)/*ε* = *F*/*k₃* + 1/*k₁*.

Fig. 1 a, The time constant (h^{-1}) of the exchange of cholesterol at 37°C between rat erythrocytes and serum lipoproteins as a function of the cell: cholesterol pool ratio F . ●, Results of cells \rightarrow serum assays; ○, results of serum \rightarrow cells assays. F values < 9 were obtained by variation of the haematocrit whereas higher values required dilution of serum. A special washing procedure¹³ was applied in order to preserve the disk shape of cells isolated from EDTA blood of fasted rats. The final medium was an oxygenated 1:1 mixture of isotonic sucrose and a slightly hypotonic 2 mM phosphate buffer with 5 mM glucose and 1 mM CaCl_2 , pH 7.4. Serum from the same rat was heated at 50°C for 45 min to block ester formation and then labelled with $\sim 0.5 \mu\text{Ci}$ purified ^3H cholesterol (specific activity 50 Ci mmol^{-1} ; Amersham) deposited on small glass beads²⁵. 4 ml of serum were labelled and used directly in the serum \rightarrow cells assays. 1 ml of labelled serum diluted twofold with the sucrose buffer medium was incubated for 2 h with 2.5 ml of packed cells for cells \rightarrow serum assays. The labelled cells were stored at 5°C overnight in the sucrose buffer medium after numerous washings. The assay was made with a vigorously shaken 2 ml cell suspension in serum or diluted serum with a 5% CO_2 atmosphere. The time intervals between collections of 6 or 7 aliquots (200 μl) were increased progressively to approach a linear change in fractional equilibria from < 0.1 to > 0.9 . After quantitative separation of cells from the serum by centrifugation and washing, the lipids were extracted after haemolysis and dilution of the two fractions. The extracts were used either for tracer measurements, liquid scintillation counting, or for chemical analyses of cholesterol, separated quantitatively from cholesteryl esters by column chromatography²⁵. Two additional aliquots per assay were used for this purpose. The time constant and tracer equilibrium for the assays were computed as described in the text. The curve shows the hyperbolic relationship between ϵ and F according to

$$\epsilon = \frac{k_1(1+F)}{1+(k_1/k_3)F}$$

with k_1 and k_3 of Table 1 computed on the basis of all the 42 assays. Also, the two asymptotes are drawn: $\epsilon = k_3$ and $F = -k_3/k_1$. **b** Shows the same data plotted according to the linear regression $1 + F/\epsilon = F(1/k_3) + 1/k_1$. The drawn regression line is $y = x(0.312 \pm 0.0084) + (4.74 \pm 0.143)$.

In a homologous system ϵ is independent of f_∞ , as $k_1 = k_3$; however ϵ is a function of f_∞ in heterologous systems, for which $k_1 \neq k_3$. Equation (7) describes an equilateral hyperbola, with $\epsilon = k_3$ and $f_\infty = -(k_3/k_1)$ as the asymptotes. The equation can be transformed into

$$\frac{1+f_\infty}{\epsilon} = f_\infty/k_3 + 1/k_1 \quad (8)$$

and k_1 and k_3 can therefore be obtained by a linear regression analysis of (ϵ, f_∞) data, using a suitable wide range of f_∞ values.

For the system of erythrocytes in serum we assign A and a to the cells, and B and b to the lipoproteins. With the cells initially labelled (cells \rightarrow serum assays) we have $a_0 = R = (a_i + b_i)$, and $b_0 = 0$. The specific rate constants of tracer dissolution, k_1 and k_3 are then assigned to the cells and the lipoproteins, respectively. In such assays, performed as described in Fig. 1 legend, the two parameters ϵ and f_∞ were computed from the b_i or $f_i = a_i/b_i$ values of a time series of aliquots. Two transforms of the left-hand side of (6) were used: $\ln(1 - b_i/b_\infty)$ or $\ln[(f_i - f_\infty)/(1 + f_i)]$. From computed values of b_∞ one immediately gets f_∞ , as $f_\infty = (R/b_\infty - 1)$. The optimal values of f_∞ (or b_∞) were obtained as the values which in the regression analysis resulted in a minimum of standard error of the time constant. The left-hand side of (6) was weighted according to the computed variances¹⁸, assuming that the coefficient of variation in the determination of f_i or b_i is equal to that of the total counts of the aliquots (3%).

This analysis has demonstrated the validity of the basic assumptions expressed in equations (1) and (2). The exchange kinetics were monophasic, within the analytical error as the data always defined the rate constant ϵ with a coefficient of variation smaller than 4% and a numerical value of the intercept of the regression line smaller than ± 0.04 . Furthermore, the regression line describes the approach to complete tracer equilibrium. The mass ratio of cholesterol, $F = A/B$, obtained by chemical analysis of cholesterol^{13,19}, and the computed f_∞ were identical, within analytical errors ($f_\infty/F = 1.001 \pm 0.045$ ($n = 14$)). Therefore F can replace f_∞ in equations (7) and (8).

In the reverse experiments (serum \rightarrow cell assays) only the

tracer uptake was used in the computation of ϵ . The procedure for labelling the lipoproteins resulted directly in the formation of a small amount of unexchangeable tracer ($< 10\%$) and therefore in erroneous f_∞ values. Thus only the chemically determined F is available for this type of assay.

The results obtained at 37°C for both types of assays are presented in Fig. 1a; the same data, plotted according to equation (8) are shown in Fig. 1b. This linear regression was used to calculate the specific rate constants k_1 and k_3 as the scatter of the 42 points of $(F, (1-F)/\epsilon)$ does not vary with F . The coefficients of variation of the reciprocal values of the two constants were obtained directly and used to calculate the s.e.m. in the estimation of rate constants. Table 1 shows the results of this analysis for all the 42 data points covering the whole range of F values and for the 18 cells \rightarrow serum as well as the 24 serum \rightarrow cells experiments separately. Clearly it makes no difference whether the initially labelled partner is serum or cells. Table 1 also shows that assays with F confined to the lower range give a well defined value for k_1 but a crude value for k_3 which is not significantly different from that calculated on the basis of all the data. The result that k_3 was much larger than k_1 was expected. According to some authors^{20,21} the hydroxyl group of cholesterol is hydrogen-bonded to the carbonyl group of lecithin, and others^{22,23} have observed that the mobility of cholesterol is less restricted in the lipoproteins. The observation that k_3 has a well defined value is perhaps surprising, considering the chemical diversities of lipoproteins. The observed monophasic exchange kinetics and the identity of the calculated f_∞ with F over the whole range of F values demonstrate; however, that the variation in k_3 within lipoproteins must be relatively small. However, the sensitivity of this criterion should not be overrated²⁴ and assays with separated lipoproteins are needed.

Equation (7) predicts that the time constant of exchange is only independent of F if $k_1 = k_3$. This is in accordance with the difference in the kinetics of homologous and heterologous systems as referred to above. If k_1 is much smaller than k_3 in heterologous systems the term $(k_1 F)/k_3$ vanishes provided the two dispersed phases contain about equal amounts of

cholesterol. The time constant of exchange then varies in proportion to $(1 + F)$, and approaches the limiting value of k_1 as F approaches zero. This prediction is again, at least qualitatively, in agreement with reported observations^{9,10,12}.

Thus the phase partition theory⁸ accounts for the exchange kinetics of homologous artificial systems as well as for the natural heterologous system in blood. The idea of transfer by collision is therefore redundant. Since the specific rate constants

k_1 and k_3 can be estimated quite accurately (Table 1) the effect of temperature will provide information on the energy by which cholesterol and probably other apolar compounds are bound in different dispersed phases.

Inge Norby Bojesen, Institute of Experimental Hormone Research and Erik Sjøntoft, Institute of Experimental Surgery, have contributed significantly to the applied mathematics and statistics. I thank Dr G. Bojesen for revising the manuscript.

Cereal seed protein is the major direct source of dietary protein for man and also serves as an indirect source through the feeding of livestock. For non-ruminant animals, such as man, swine and poultry, most cereal seed proteins are deficient in lysine and threonine and much effort has been devoted to their improvement¹. Supplementation of barley diets for pigs with lysine and threonine is sufficient to produce a feed with protein of high biological value². Mutant lines that accumulate these amino acids in the seed could therefore be of agricultural value. The synthesis of lysine, threonine and methionine, which are all derived from aspartic acid, is regulated in plants by a series of feedback loops^{3,4}. This regulation is such that when barley embryos are germinated on a medium containing lysine plus threonine (LT medium) the plants are starved of methionine and fail to grow⁵. Plants which do grow in these conditions may contain enzymes that are no longer feedback-regulated and that may allow enhanced amounts of end-product amino acids to accumulate. We report here the identification of two genes in barley, mutations in which lead to decreased feedback sensitivity of the enzyme aspartate kinase, resistance to lysine plus threonine and, in some cases, to accumulation of soluble threonine in the seed.

From an M_2 population of 10^4 mature embryos (M_1 treated with sodium azide) three mutants resistant to lysine plus threonine (2–3 mM) were selected for further study. These were R(Rothamsted) 2501 (ref. 6), R3004 and R3202 which produced sensitive and resistant progeny in the M_3 generation. Pure-breeding resistant lines were obtained from R3004 and R3202 and, with difficulty, from R2501. The designation R3004 or R3202 refers henceforth to the M_3 and subsequent generations of such lines.

Both R3202 and R3004 plants grew better than controls in a range of concentrations of lysine and threonine (Fig. 1). R3202 plants were generally larger and had better root growth than R3004. Both mutant lines had lost the synergistic inhibition of growth by lysine plus threonine (Fig. 2) but were still slightly inhibited by lysine alone. This was reduced by addition of arginine. Neither R3202 nor R3004 were resistant to the lysine analogue S-(2-aminoethyl)cysteine.

To characterize the genetic basis of resistance, mutant plants were crossed among themselves and with normal barley cv. Golden Promise. Crosses with Golden Promise (Table 1) showed a segregation of three resistant to one sensitive in the F_2 generation, consistent with resistance in each case being due to the action of a single dominant nuclear gene. When R3202 and R3004 were reciprocally crossed, in the F_2 generation a ratio of 15 resistant plants to 1 sensitive plant was observed (Table 1), suggesting that the two genes *Lt1b* and *Lt2* are unlinked. Progeny of single F_1 plants of reciprocal crosses of heterozygous R2501-derived plants (*Lt1a/+*) with R3202 (*Lt1b/Lt1b*) were scored in the same way for resistance (Table 1). Three plants (C, D and E) gave no sensitive progeny in the F_2 generation, suggesting that they had received a resistance gene from each parent and that these two genes are allelic or closely linked. However, two plants (A and B) produced sensitive progeny, suggesting that they had received the wild-type sensitive gene from R2501; this hypothesis is supported for A by the segregation ratio of 33:8 (not significantly different from 3:1) and for B by the finding that, when 13 of the 15 resistant F_2 plants were self-pollinated and their F_3 progeny tested, 9 of them gave rise to some sensitive plants (pooled data 108:44 not significantly different from 3:1). No segregation data are available for the cross R2501 × R3004.
